HEMATOLOGY

BASIC PRINCIPLES AND PRACTICE

SIXTH EDITION

Ronald Hoffman MD

Albert A. and Vera G. List Professor of Medicine, Tisch Cancer Institute, Department of Medicine, Mount Sinai School of Medicine, New York, New York

Edward J. Benz, Jr. MD

President and Chief Executive Officer, Dana-Farber Cancer Institute, Director and Principal Investigator, Harvard Cancer Center; Richard and Susan Smith Professor of Medicine, Professor of Pediatrics and Genetics, Harvard Medical School, Boston, Massachusetts

Leslie E. Silberstein MD

Director, Joint Program in Transfusion Medicine, Children's Hospital Boston; Director, Center for Human Cell Therapy, Boston, Massachusetts

Helen E. Heslop MD

Dan L. Duncan Chair, Professor of Medicine and Pediatrics; Director, Adult Stem Cell Transplant Program, Center for Cell and Gene Therapy, Baylor College of Medicine, The Methodist Hospital, Texas Children's Hospital, Houston, Texas

Jeffrey I. Weitz MD

Professor of Medicine and Biochemistry, McMaster University; HSFO/J.F. Mustard Chair in Cardiovascular Research; Canada Research Chair (Tier 1) in Thrombosis; Executive Director, Thrombosis & Atherosclerosis Research Institute, Hamilton, Ontario, Canada

John Anastasi MD

Associate Professor, Department of Pathology, University of Chicago, Chicago, Illinois

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence, or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER BOOK AID International Sabre Foundation

To the numerous authors who have toiled to create the timely and outstanding chapters that comprise this book. Their energy and perseverance is emblematic of their personal character and continued commitment to the value of scholarship and education in medicine. The work of each of these authors enhances the knowledge of practicing and research hematologists, which results in better care for patients with blood disorders. I would also like to recognize the continued support of my wife, Nan, and my children, Michael and Judith, who have encouraged me to continue this pursuit. This edition would not have happened without the continued support of the staff at Elsevier, especially Lucia Gunzel, who has made this book a reality. I would also like to acknowledge my colleagues at Mount Sinai School of Medicine who continue to value the contribution that this book represents. Last, but not least, our loyal readers, who have made this book a success for more than 20 years and continue to value and use it in a manner that enhances their professional pursuits.

Ronald Hoffman, MD

To my wife, Peggy, for your support, inspiration, and partnership; to our children, Tim, Jenny, Julie, and Rob, for your understanding; to my mentors, for your support and guidance; to Sharon Olsen, for your incredible skill, patience, and good humor throughout this project; and to the many patients and volunteers whose willingness to participate in clinical research made much of the knowledge conveyed by this book possible.

Edward J. Benz, Jr., MD

To my friends and family for their love and support; to my mentors, Eugene M. Berkman and Robert S. Schwartz, who have provided me with invaluable guidance; to my colleagues at the University of Pennsylvania and Harvard, who have helped me develop academic transfusion medicine programs; and to the trainees who make this endeavor enjoyable and worthwhile.

Leslie E. Silberstein, MD

To my family, friends, and all of my present and former colleagues and trainees for their support and encouragement; to all my mentors in hematology who have provided guidance, in particular, Michael Beard and Malcolm Brenner.

Helen E. Heslop, MD

To my wife, Julia, for her love and unwavering support: I would be lost without her; to my children, Daniel and Caileen, for their understanding and encouragement; to Gwen, for extending our family; to my colleagues for providing me with an environment for learning and growth; and to my trainees, for making this all worthwhile.

Jeffrey I. Weitz, MD

To my respected clinical colleagues with appreciation for trusting me with the diagnostic material from their patients; to my esteemed teachers, Jim Vardiman, Diana Variakojis, and from long ago, C. Robert Valeri, for your many lessons focused on things at both ends of the microscope; and to my awesome trainees; it is always a great pleasure to watch you grow to appreciate the serious, yet amazing, nature of our work.

John Anastasi, MD

CONTRIBUTORS

Janet L. Abrahm MD
Division Chief, Adult Palliative Care, Department of Psychosocial Oncology and Palliative Care, Dana-Farber Cancer Institute; Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Indwelling Access Devices
Pain Management and Antiemetic Therapy in Hematologic Disorders
Palliative Care

Charles S. Abrams MD
Professor of Medicine, Division of Hematology and Oncology, University of Pennsylvania, Philadelphia, Pennsylvania
Molecular Basis for Platelet Function

Donald I. Abrams MD
Chief, Hematology and Oncology, San Francisco General Hospital, Integrative Oncology, University of California San Francisco Osher Center for Integrative Medicine, San Francisco, California
Integrative Therapies in Patients With Hematologic Diseases

Steven J. Ackerman PhD
Professor of Biochemistry and Molecular Genetics, and Medicine, Department of Biochemistry and Molecular Genetics, College of Medicine, University of Illinois at Chicago, Chicago, Illinois
Eosinophilia, Eosinophil-Associated Diseases, Chronic Eosinophil Leukemia, and the Hypereosinophilic Syndromes

Sharon Adams MT, CHS (ABHI)
National Institutes of Health, Clinical Center, Department of Transfusion Medicine, Human Leukocyte Antigen Laboratory Supervisor, Bethesda, Maryland
Human Leukocyte Antigen and Human Neutrophil Antigen Systems

Adeboye H. Adewoye MD
Assistant Professor of Medicine, Boston University School of Medicine; Attending Physician, Boston Medical Center, Boston, Massachusetts
Pathobiology of the Human Erythrocyte and Its Hemoglobins

Carl Allen MD, PhD
Assistant Professor, Department of Pediatrics, Texas Children's Cancer Center, Texas Children's Hospital, Baylor College of Medicine, Houston, Texas
Infectious Mononucleosis and Other Epstein-Barr Virus–Associated Diseases

Richard F. Ambinder MD, PHD
Murphy Professor of Oncology; Professor, Departments of Oncology, Medicine, Pathology, and Pharmacology; Director, Division of Hematologic Malignancies, Department of Oncology, Johns Hopkins School of Medicine, Baltimore, Maryland
Virus-Associated Lymphoma

Claudio Anasetti MD
Chair, Department of Blood and Marrow Transplantation, Moffitt Cancer Center, Tampa, Florida
Unrelated Donor Hematopoietic Cell Transplantation

John Anastasi MD
Associate Professor, Department of Pathology, University of Chicago, Chicago, Illinois
Progress in the Classification of Myeloid Neoplasms: Clinical Implications
Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas

Julia A. Anderson MD

Indications and Outcome of Allogeneic Hematopoietic Cell Transplantation for Hematologic Malignancies in Adults

Edwin M. Horwitz MD, PhD
Associate Professor of Pediatrics, Department of Pediatrics and Oncology, University of Pennsylvania Perelman School of Medicine, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Mesenchymal Stromal Cells

Robert A. Hromas MD
Professor and Chair, Department of Medicine, University of Florida College of Medicine, Gainesville, Florida
Regulation of Gene Expression, Transcription, Splicing, and RNA Metabolism

Franklin W. Huang MD, PhD
Clinical Fellow, Department of Hematology and Medical Oncology, Dana-Farber Cancer Institute, Brigham and Women's Hospital, Massachusetts General Hospital, Boston, Massachusetts
Indwelling Access Devices

David E. Isenman PhD
Professor Emeritus, Departments of Biochemistry and Immunology, University of Toronto, Toronto, Ontario, Canada*Complement and Immunoglobulin Biology*

Joseph E. Italiano, Jr. PhD
Associate Professor, Department of Medicine, Brigham and Women's Hospital; Associate Professor, Harvard Medical School; Assistant Professor, Department of Surgery, Vascular Biology Program, Children's Hospital Boston, Boston, Massachusetts
Megakaryocyte and Platelet Structure

Elaine S. Jaffe MD
Head, Hematopathology Section, Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland
Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas

Sundar Jagannath MD
Director, Multiple Myeloma Program, Mount Sinai Medical Center; Professor, Department of Hematology and Medical Oncology, Tisch Cancer Institute, Mount Sinai School of Medicine, New York, New York
Plasma Cell Neoplasms

Ulrich Jäger MD
Professor of Hematology; Head, Division of Hematology and Hemostaseology, Department of Medicine, Medical University of Vienna, Comprehensive Cancer Center, Vienna, Austria*Autoimmune Hemolytic Anemia*

Nitin Jain MD
Department of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas
Acute Lymphoblastic Leukemia in Adults

Paula James MD
Associate Professor, Department of Medicine, Queen's University, Kingston, Ontario, Canada
Structure, Biology, and Genetics of von Willebrand Factor

Sima Jeha MD
Director, Leukemia and Lymphoma Developmental Therapeutics, Department of Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee
Clinical Manifestations and Treatment of Acute Lymphoblastic Leukemia in Children

Michael B. Jordan MD
Associate Professor of Pediatrics, Divisions of Immunobiology and Bone Marrow Transplant and Immunodeficiency, Department of Pediatrics, Cincinnati Children's Hospital, University of Cincinnati, Cincinnati, Ohio
Histiocytic Disorders

Cassandra Josephson MD
Associate Professor, Department Pathology and Pediatrics, Emory University School of Medicine; Director, Clinical Research, Center for Transfusion and Cellular Therapies; Program Director, Transfusion Medicine Fellowship; Medical Director, Children's Healthcare of Atlanta Blood and Tissue Services, Atlanta, Georgia
Pediatric Transfusion Medicine

Moonjung Jung MD
Fellow, Hematology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland
Neutrophilic Leukocytosis, Neutropenia, Monocytosis, and Monocytopenia

Leo Kager MD
Associate Professor of Pediatrics, Department of Hematology and Oncology, St. Anna Children's Hospital, Department of Pediatrics, Medical University of Vienna, Children's Cancer Research Institute, Vienna, Austria
Pharmacogenomics and Hematologic Diseases

Kala Y. Kamdar MD
Section of Hematology and Oncology, Department of Pediatrics, Baylor College of Medicine, Houston, Texas
Malignant Lymphomas in Childhood

Jennifer A. Kanakry MD
Hematology Fellow, Department of Hematology, Johns Hopkins Hospital, Baltimore, Maryland
Virus-Associated Lymphomas

Hagop M. Kantarjian MD
Professor, Department of Leukemia, Division of Cancer Medicine, Associate Vice President for Global Academic Programs, Department Chair, Kelcie Margaret Kana Research Chair, Department of Leukemia, Division of Cancer Medicine, The University of Texas MD Anderson Cancer Center, Houston, Texas
Clinical Manifestations and Treatment of Acute Myeloid Leukemia

Matthew S. Karafin MD
Transfusion Medicine Fellow, Department of Pathology, Johns Hopkins Hospital, Baltimore, Maryland
Principles of Plasma Transfusion: Plasma, Cryoprecipitate, Albumin, and Immunoglobulins

Aly Karsan MD
Professor, Pathology and Laboratory Medicine, University of British Columbia; Hematopathologist/Senior Scientist, British Columbia Cancer Agency, Vancouver, British Columbia, Canada
The Blood Vessel Wall

Louis M. Katz MD
Executive Vice President, Mississippi Valley Regional Blood Center, Davenport, Iowa; Adjunct Clinical Professor, Department of Internal Medicine, Division of Infectious Diseases, Carver College of Medicine, University of Iowa, Iowa City, Iowa
Transfusion-Transmitted Diseases

Randal J. Kaufman PhD
Director, Del E. Webb Neuroscience, Aging, and Stem Cell Research Center, Sanford Burnham Medical Research Institute, La Jolla, California
Protein Synthesis, Processing, and Trafficking

Richard M. Kaufman MD
Medical Director, Adult Transfusion Service, Brigham and Women's Hospital; Assistant Professor of Pathology, Harvard Medical School, Boston, Massachusetts
Principles of Platelet Transfusion Therapy
Transfusion Medicine in Hematopoietic Stem Cell and Solid Organ Transplantation

Frank G. Keller MD
Associate Professor of Pediatrics, Emory University School of Medicine, Aflac Cancer Center and Blood Disorders Service, Atlanta, Georgia
Hematologic Manifestations of Childhood Illness

Kara M. Kelly MD
Professor of Clinical Pediatrics, Division of Pediatric Oncology, Columbia University Medical Center, New York, New York
Integrative Therapies in Patients With Hematologic Diseases

John Kelton MD
Professor of Medicine and Pathology and Molecular Medicine, McMaster University, Michael G. DeGroote School of Medicine, Hamilton, Ontario, Canada
Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

Craig M. Kessler MD
Professor of Medicine and Pathology; Director, Division of Coagulation, Hemophilia and Thrombosis Comprehensive Care Center, Georgetown University Medical Center, Washington, DC
Inhibitors in Hemophilia A and B

Nigel S. Key MB, ChB
Harold R. Roberts Distinguished Professor, Department of Medicine and Pathology and Laboratory Medicine; Chief, Section of Hematology, Division of Hematology and Oncology; Director, Hemophilia and Thrombosis Center, University of North Carolina, Chapel Hill, North Carolina
Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Alexander G. Khandoga MD
Department of Cardiology, German Heart Center Munich, Munich, Germany
Hematopoietic Cell Trafficking and Chemokines

Arati Khanna-Gupta MSc, PhD
Assistant Professor, Division of Adult Hematology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Granulocytopoiesis and Monocytopoiesis

Harvey G. Klein MD
Chief, Department of Transfusion Medicine, W.G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland
Hemapheresis

Orit Kollet PhD
Associate Scientist, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel
Dynamic Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Barbara A. Konkle MD
Director, Translational Research; Medical Director, Hemostasis Reference Laboratory, Puget Sound Blood Center; Professor of Medicine and Hematology, University of Washington, Seattle, Washington
Inhibitors in Hemophilia A and B

Dimitrios P. Kontoyiannis MD
Frances King Black Endowed Professor, Infectious Diseases, Deputy Head, Division of Internal Medicine, The University of Texas MD Anderson Cancer Center, Houston, Texas
Clinical Approach to Infections in the Compromised Host

John Koreth MBBS, DPhil
Assistant Professor, Department of Medical Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts
Allogeneic Hematopoietic Stem Cell Transplantation for Acute Myeloid Leukemia and Myelodysplastic Syndrome in Adults

Gary A. Koretzky MD, PhD
Francis C. Wood Professor of Medicine, Department of Medicine, Division of Rheumatology, Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, Pennsylvania
T-Cell Immunity

Marina Kremyanskaya MD, PhD
Assistant Professor of Medicine, Tisch Cancer Institute, Department of Medicine, Mount Sinai School of Medicine, New York, New York
The Polycythemias
Essential Thrombocythemia
Primary Myelofibrosis
Eosinophilia, Eosinophil-Associated Diseases, Chronic Eosinophil Leukemia, and the Hypereosinophilic Syndromes
Mast Cells and Systemic Mastocytosis

Ralf Küppers PhD
Professor, Institute of Cell Biology and Cancer Research, University of Duisburg-Essen Medical School, Essen, Germany
Origin of Hodgkin Lymphoma

Timothy M. Kuzel MD, RACP
Professor, Division of Hematology and Oncology, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois
T-Cell Lymphomas

Larry W. Kwak MD
Professor and Chair, Department of Lymphoma and Myeloma, The University of Texas MD Anderson Cancer Center, Houston, Texas
Mantle Cell Lymphoma

Viswanathan Lakshmanan PhD
Postdoctoral Scientist, Department of Microbiology and Immunology, Columbia University Medical Center, New York, New York
Dendritic Cell Biology

Wendy Landier PhD, RN
Clinical Director, Center for Cancer Survivorship, Department of Population Sciences, City of Hope Comprehensive Cancer Center, Duarte, California*Late Complications of Hematologic Diseases and Their Therapies*

Kfir Lapid PhD
Associate Scientist, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel
Dynamic Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Tsvee Lapidot PhD
Professor, Department of Immunology, Weizmann Institute of Science, Rehovot, Israel
Dynamic Interactions Between Hematopoietic Stem and Progenitor Cells and the Bone Marrow: Current Biology of Stem Cell Homing and Mobilization

Peter J. Larson
Director, Global Clinical Strategy, Biological Products, Research Triangle Park, North Carolina
Transfusion Therapy for Coagulation Factor Deficiencies

Klaus Lechner MD
Professor Emeritus of Medicine and Hematology, Department of Medicine, Division of Hematology and Hemostaseology, Medical University of Vienna, Vienna, Austria
Autoimmune Hemolytic Anemia

Andrea Lee MD
Associate Staff, Department of Medicine, Division of Hematology, Oakville-Trafalgar Memorial Hospital, Oakville, Ontario, Canada
Hematologic Manifestations of Liver Disease

William M.F. Lee MD, PhD
Associate Professor of Medicine, Department of Medicine, Division of Hematology and Oncology; Co-Program Leader, Tumor Biology, Abramson Cancer Center, University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Control of Cell Division

Marcel Levi MD, PhD
Professor of Medicine, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands
Disseminated Intravascular Coagulation

Russell E. Lewis PharmD
Professor, University of Houston College of Pharmacy, The University of Texas MD Anderson Cancer Center, Houston, Texas
Clinical Approach to Infections in the Compromised Host

Howard A. Liebman MA, MD
Professor of Medicine and Pathology, Jane Anne Nohl Division of Hematology and Center for the Study of Blood Diseases, University of Southern California Keck School of Medicine, Los Angeles, California
Hematologic Manifestations of HIV/AIDS

David Lillicrap MD
Professor, Department of Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada
Hemophilia A and B

Wendy Lim MD
Associate Professor, Department of Medicine, McMaster University, Hamilton, Ontario, Canada
Venous Thromboembolism
Hematologic Manifestations of Liver Disease

Thomas S. Lin MD
Associate Professor of Medicine, Ohio State University, Columbus, Ohio
Chronic Lymphocytic Leukemia

Robert Lindblad MD
Chief Medical Officer, The EMMES Corporation, Rockville, Maryland
Preclinical Process of Cell-Based Therapies

Gregory Y.H. Lip MD
Professor of Cardiovascular Medicine, University of Birmingham, Center for Cardiovascular Sciences, City Hospital, Birmingham, United Kingdom
Atrial Fibrillation

Jane A. Little MD
Associate Professor, Department of Medicine, University Hospitals Seidman Cancer Center, Case Western Reserve University, Cleveland, Ohio
Anemia of Chronic Diseases

Mignon L. Loh MD
Professor of Clinical Pediatrics, University of California San Francisco, Benioff Children's Hospital, Helen Diller Family Comprehensive Cancer Center, San Francisco, California
Myelodysplastic and Myeloproliferative Neoplasms in Children

A. Thomas Look MD
Professor of Pediatrics, Harvard Medical School, Vice-Chair for Research, Department of Pediatric Oncology, Division of Hematology and Oncology, Dana-Farber Cancer Institute, Children's Hospital Boston, Boston, Massachusetts
Pathobiology of Acute Lymphoblastic Leukemia

José A. López MD
Executive Vice-President for Research, Research Institute, Puget Sound Blood Center; Professor, Departments of Medicine and Biochemistry, University of Washington, Seattle, Washington
Acquired Disorders of Platelet Function

Francis W. Luscinskas PhD
Professor, Department of Pathology; Associate Director, Vascular Research Division, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Cell Adhesion

Christine A. Macartney MB, DCH, MRCP
Department of Pediatric Hematology, Royal Belfast Hospital for Sick Children, Belfast, Northern Ireland, United Kingdom
Disorders of Coagulation in the Neonate

Jaroslaw P. Maciejewski MD, PhD
Chairman and Professor of Medicine, Department of Translational Hematology and Oncology Research, Taussig Cancer Center, Cleveland Clinic, Cleveland, Ohio
Aplastic Anemia
Acquired Disorders of Red Cell, White Cell, and Platelet Production

Robert W. Maitta MD, PhD
Assistant Director of Transfusion Medicine, Blood Bank and Donor Apheresis Center; Assistant Professor, Department of Pathology, Case Western Reserve University, University Hospitals, Case Medical Center, Cleveland, Ohio
Transfusion Reactions to Blood and Cell Therapy Products

Navneet S. Majhail MD, MS
Medical Director, National Marrow Donor Program, Adjunct Associate Professor of Medicine, University of Minnesota, Minneapolis, Minnesota
Complications After Hematopoietic Stem Cell Transplantation

Olivier Manches PhD
Research Assistant, New York University School of Medicine, Langone Medical Center, New York, New York
Dendritic Cell Biology

Robert Mandle PhD
President, BioSciences Research Associates, Inc., Cambridge, Massachusetts
Complement and Immunoglobulin Biology

Kenneth G. Mann PhD
Departments of Biochemistry and Medicine, University of Vermont College of Medicine, Burlington, Vermont
Molecular Basis of Blood Coagulation

Catherine S. Manno MD
Pat and John Rosenwald Professor and Chair, Department of Pediatrics, New York University School of Medicine, New York, New York
Transfusion Therapy for Coagulation Factor Deficiencies

Enrica Marchi MD
Postdoctoral Fellow, New York University Cancer Institute, New York, New York
T-Cell Lymphomas

Guglielmo Mariani MD
Department of Internal Medicine, Section of Hematology, University of L'Aquila, Italy
Inhibitors in Hemophilia A and B

Francesco M. Marincola MD
Department of Transfusion Medicine, Clinical Center for Human Immunology, National Institutes of Health, Bethesda, Maryland
Human Leukocyte Antigen and Human Neutrophil Antigen Systems

Peter W. Marks MD, PhD
Associate Professor of Medicine, Department of Internal Medicine, Yale University School of Medicine, New Haven, Connecticut
Approach to Anemia in the Adult and Child
Hematologic Manifestations of Systemic Disease: Renal Disease

John Mascarenhas MD
Assistant Professor of Medicine, Tisch Cancer Institute, Department of Medicine, Mount Sinai School of Medicine, New York, New York
The Polycythemias
Essential Thrombocythemia
Primary Myelofibrosis
Eosinophilia, Eosinophil-Associated Diseases, Chronic Eosinophil Leukemia, and the Hypereosinophilic Syndromes
Mast Cells and Systemic Mastocytosis

Steffen Massberg MD
Professor of Cardiology, German Heart Center Munich, Technical University of Munich, Munich, Germany
Hematopoietic Cell Trafficking and Chemokines

Peter M. Mauch MD
Professor of Radiation Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts
Radiation Therapy in the Treatment of Hematologic Malignancies

Ruth McCorkle PhD, RN, FAAN
Florence Wald Professor of Nursing, Yale University School of Nursing, New Haven, Connecticut
Psychosocial Aspects of Hematologic Disorders

Keith R. McCrae MD
Professor of Molecular Medicine, Cleveland Clinic Lerner College of Medicine, Taussig Cancer Institute, Cleveland Clinic, Cleveland, Ohio
Thrombotic Thrombocytopenic Purpura and the Hemolytic Uremic Syndrome

Rodger P. McEver MD
Cardiovascular Biology Research Program, Oklahoma Medical Research Foundation, Department of Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma
Cell Adhesion

Emer McGrath
Health Research Board Clinical Research Facility, National University of Ireland, Galway, Ireland
Stroke

Matthew S. McKinney MD
Fellow, Hematology and Oncology, Departments of Medicine and Cellular Therapy, Division of Oncology, Duke University, Durham, North Carolina
Origin of Non-Hodgkin Lymphoma

Amy Meacham MS
Senior Biological Scientist, Department of Medicine, Division of Hematology and Oncology, University of Florida College of Medicine, Gainesville, Florida
Regulation of Gene Expression, Transcription, Splicing, and RNA Metabolism

Jay E. Menitove MD
Clinical Professor of Pathology and Laboratory Medicine, University of Kansas School of Medicine, Kansas City, Kansas; Clinical Professor of Internal Medicine, University of Missouri-Kansas City School of Medicine; President, Chief Executive Officer, and Medical Director, Community Blood Center of Greater Kansas City, Kansas City, Missouri
Transfusion-Transmitted Diseases

Giampaolo Merlini MD
Director, Amyloidosis Research and Treatment Center, Foundation IRCCS Policlinico San Matteo, Department of Molecular Medicine, University of Pavia, Pavia, Italy
Waldenström Macroglobulinemia and Lymphoplasmacytic Lymphoma

Anna Rita Migliaccio MD
Professor of Medicine, Tisch Cancer Center, Mount Sinai School of Medicine, New York, New York
Biology of Erythropoiesis, Erythroid Differentiation, and Maturation

Jeffrey S. Miller MD
Professor of Medicine, Department of Medicine, Division of Hematology, Oncology, and Transplantation, University of Minnesota, Minneapolis, Minnesota
Natural Killer Cell-Based Therapies

Martha P. Mims MD, PhD
Associate Professor of Medicine; Chief, Department of Internal Medicine, Section of Hematology and Oncology, Baylor College of Medicine, Houston, Texas
Lymphocytosis, Lymphocytopenia, Hypergammaglobulinemia, and Hypogammaglobulinemia

Traci Heath Mondoro PhD
Deputy Branch Chief, Transfusion Medicine and Cellular Therapeutics, Division of Blood Diseases and Resources, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland
Preclinical Process of Cell-Based Therapies

Paul Moorehead MD
Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada
Hemophilia A and B

Nikhil C. Munshi MD
Associate Professor of Medicine, Harvard Medical School, Dana-Farber Cancer Institute, Boston, Massachusetts
Plasma Cell Neoplasms

Vesna Najfeld PhD
Professor of Pathology and Medicine, Departments of Pathology and Medicine; Director, Tumor Cytogenetics and Oncology, Molecular and Cellular Tumor Markers, Tisch Cancer Institute, Mount Sinai School of Medicine, New York, New York
Conventional and Molecular Cytogenetic Basis of Hematologic Malignancies
The Polycythemias
Essential Thrombocythemia
Primary Myelofibrosis

Ishac Nazi PhD
Assistant Professor, Biochemistry and Biomedical Sciences, McMaster University, Platelet Immunology, Hamilton, Ontario, Canada
Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

Anne T. Neff MD
Associate Professor of Medicine and Pathology, Microbiology, and Immunology; Director, Hemostasis and Thrombosis Clinic, Vanderbilt University Medical Center, Nashville, Tennessee
Rare Coagulation Factor Deficiencies

Paul M. Ness MD
Director, Transfusion Medicine, Department of Pathology, Johns Hopkins Hospital; Professor of Pathology, Medicine, and Oncology, Johns Hopkins University School of Medicine, Baltimore, Maryland
Principles of Red Blood Cell Transfusion

Andrea K. Ng MD, MPH
Associate Professor of Radiation Oncology, Dana-Farber Cancer Institute, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Radiation Therapy in the Treatment of Hematologic Malignancies

Luigi D. Notarangelo MD
Professor of Pediatrics and Pathology, Department of Medicine, Division of Immunology, Children's Hospital Boston, Harvard Medical School, Boston, Massachusetts
Congenital Disorders of Lymphocyte Function

Sarah H. O'Brien MD, MSc
Assistant Professor of Pediatrics, Division of Pediatric Hematology and Oncology, Nationwide Children's Hospital, Ohio State University, Columbus, Ohio
Hematologic Manifestations of Childhood Illness

Owen A. O'Connor MD, PhD
Associate Professor of Medicine, Director, Lymphoid Development and Malignancy Program, Herbert Irving Comprehensive Cancer Center, Columbia University; Chief, Lymphoma Service, College of Physicians and Surgeons, Presbyterian Hospital, Columbia University Medical Center, New York, New York
T-Cell Lymphomas

Diarmaid Ó Donghaile MD
Clinical Fellow, Department of Transfusion Medicine, W.G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland
Hemapheresis

Martin O'Donnell MD
Population Health Research Institute, Hamilton General Hospital, McMaster University, Hamilton, Ontario, Canada
Stroke

Stavroula Otis MD
Clinical Instructor, Department of Medicine and Hematology, Stanford University School of Medicine, Palo Alto, California
Red Blood Cell Enzymopathies

Zhishuo Ou MD
Instructor, Department of Lymphoma and Myeloma, The University of Texas MD Anderson Cancer Center, Houston, Texas
Mantle Cell Lymphoma

Sung-Yun Pai MD
Assistant Professor, Division of Hematology and Oncology, Children's Hospital Boston, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts
Congenital Disorders of Lymphocyte Function

Karolina Palucka MD, PhD
Investigator, Baylor Institute for Immunology Research, Dallas, Texas; Professor, Department of Oncological Sciences, Mount Sinai School of Medicine, New York, New York
Dendritic Cell Therapies

Reena L. Pande MD
Brigham and Women's Hospital, Cardiovascular Division, Instructor in Medicine, Harvard Medical School, Boston, Massachusetts
Peripheral Artery Disease

Thalia Papayannopoulou MD
Professor of Medicine, Division of Hematology, Department of Medicine, University of Washington, Seattle, Washington
Biology of Erythropoiesis, Erythroid Differentiation, and Maturation

Animesh Pardanani MBBS, PhD
Department of Hematology, Mayo Clinic, Rochester, Minnesota
Mast Cells and Systemic Mastocytosis

Nethnapha Paredes
Department of Pediatrics, McMaster University, Hamilton, Ontario, Canada
Disorders of Coagulation in the Neonate

Christopher Patriquin BHSc, MD
Hematology Fellow, Department of Medicine, Division of Hematology and Thromboembolism, McMaster University, Hamilton, Ontario, Canada
Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

Effie W. Petersdorf MD
Professor of Medicine, University of Washington; Member, Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, Washington
Unrelated Donor Hematopoietic Cell Transplantation

Stefania Pittaluga MD, PhD
Staff Clinician, Hematopathology Section, Laboratory of Pathology, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland
Pathologic Basis for the Classification of Non-Hodgkin and Hodgkin Lymphomas

Edward F. Plow PhD
Professor of Molecular Medicine, Cleveland Clinic Lerner College of Medicine; Chairman, Robert C. Tarazi, MD Endowed Chair in Heart and Hypertension Research, Department of Molecular Cardiology, Joseph J. Jacobs Center for Thrombosis and Vascular Biology, Lerner Research Institute, Cleveland Clinic, Cleveland, Ohio
Molecular Basis for Platelet Function

Doris M. Ponce MD
Assistant Professor, Medicine, Adult Bone Marrow Transplantation, Memorial Sloan-Kettering Cancer Center, New York, New York
Unrelated Donor Cord Blood Transplantation for Hematologic Malignancies

Laura Popolo PhD
Associate Professor of Molecular Biology, Department of Biomolecular Sciences and Biotechnology, University of Milan, Milan, Italy
Protein Synthesis, Processing, and Trafficking

Leland D. Powell MD, PhD
Professor of Medicine, Department of Medicine, Olive View University of California Los Angeles Medical Center, Sylmar, California; Health Sciences Clinical Professor of Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, California
Overview and Compartmentalization of the Immune System

Elizabeth A. Price MD, MPH
Assistant Professor, Department of Medicine, Division of Hematology, Stanford University School of Medicine, Palo Alto, California
Red Blood Cell Enzymopathies
Extrinsic Nonimmune Hemolytic Anemias

Ching-Hon Pui MD
Member; Chair, Department of Oncology; Co-Leader, Hematological Malignancies Program; Fahad Nassar Al-Rashid Chair of Leukemia Research; American Cancer Society Professor, St. Jude Children's Research Hospital, Memphis, Tennessee
Clinical Manifestations and Treatment of Acute Lymphoblastic Leukemia in Children

Pere Puigserver PhD
Associate Professor, Departments of Cancer Biology and Cell Biology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts
Signaling Transduction and Regulation of Cell Metabolism

Alfonso Quintás-Cardama MD
Assistant Professor, Division of Cancer Medicine, Department of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas
Pathobiology of Acute Myeloid Leukemia

Janusz Rak MD, PhD
Professor, Department of Pediatrics; Jack Cole Chair in Pediatric Hematology and Oncology, McGill University, Research Institute of the McGill University Health Center, Montreal Children's Hospital, Montreal, Quebec, Canada
Vascular Growth in Health and Disease

Carlos A. Ramos MD
Assistant Professor, Center for Cell and Gene Therapy, Department of Medicine, Hematology and Oncology Section, Baylor College of Medicine, Houston, Texas
Clinical Manifestations and Treatment of Marginal Zone Lymphomas (Extranodal/MALT, Splenic, and Nodal)

Jacob H. Rand MD
Professor of Pathology and Medicine, Albert Einstein College of Medicine, Montefiore Medical Center, Bronx, New York
Antiphospholipid Syndrome

Farhad Ravandi MD
Professor of Medicine, Department of Leukemia, The University of Texas MD Anderson Cancer Center, Houston, Texas
Hairy Cell Leukemia

David J. Rawlings MD
Children's Guild Association Endowed Chair in Pediatric Immunology; Director, Center for immunity and Immunotherapies, Seattle Children's Research Institute; Chief, Division of Immunology, Seattle Children's Hospital; Professor of Pediatrics and Immunology, University of Washington School of Medicine, Seattle, Washington
B-Cell Development

Pavan Reddy MD
Associate Division Chief, Hematology and Oncology; Co-Director, Hematologic Malignancies and Bone Marrow Transplant Program, University of Michigan Cancer Center, Ann Arbor, Michigan
Graft-Versus-Host Disease and Graft-Versus-Leukemia Responses

Mark T. Reding MD
Associate Professor of Medicine, Division of Hematology, Oncology, and Transplantation; Director, Center for Bleeding and Clotting Disorders, University of Minnesota Medical Center, Minneapolis, Minnesota
Hematologic Problems in the Surgical Patient: Bleeding and Thrombosis

Charles Rhee MD
Department of Medicine, University of Chicago, Chicago, Illinois
Acute Lymphoblastic Leukemia in Adults

Lawrence Rice MD
Professor of Medicine, Weill Cornell Medical College; Chief of Hematology, Department of Medicine, Methodist Hospital; Adjunct Professor of Medicine, Baylor College of Medicine, Houston, Texas
Neutrophilic Leukocytosis, Neutropenia, Monocytosis, and Monocytopenia

Matthew J. Riese MD
Division of Hematology and Oncology, Department of Medicine, Abramson Family Cancer Research Institute, University of Pennsylvania, Philadelphia, Pennsylvania
T-Cell Immunity

Arthur Kim Ritchey MD
Chief, Division of Pediatric Hematology and Oncology, Children's Hospital, University of Pittsburgh Medical Center; Professor of Pediatrics, Vice-Chair for Clinical Affairs, Department of Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Hematologic Manifestations of Childhood Illness

Stefano Rivella PhD
Associate Professor of Genetic Medicine, Departments of Pediatrics and Cell and Developmental Biology, Division of Hematology and Oncology, Weill Cornell Medical College, New York, New York
Thalassemia Syndromes

David J. Roberts MBChB, DPhil
Consultant Hematologist, National Health Service Blood and Transplant; Professor of Hematology, University of Oxford, Oxford, United Kingdom
Hematologic Aspects of Parasitic Diseases

Jorge E. Romaguera MD
Professor, Department of Lymphoma and Myeloma, The University of Texas MD Anderson Cancer Center, Houston, Texas
Mantle Cell Lymphoma

Elizabeth Roman MD
Assistant Professor of Pediatrics, Division of Pediatric Hematology and Oncology, New York University School of Medicine, New York, New York
Transfusion Therapy for Coagulation Factor Deficiencies

Cliona M. Rooney PhD
Professor, Departments of Pediatrics, Molecular Virology and Microbiology, and Pathology and Immunology, Center for Cell and Gene Therapy, Texas Children's Cancer Center, Texas Children's Hospital, The Methodist Hospital, Baylor College of Medicine, Houston, Texas
Infectious Mononucleosis and Other Epstein-Barr Virus–Associated Diseases

Steven T. Rosen MD
Professor of Medicine, Northwestern University Feinberg School of Medicine; Director, Robert H. Lurie Comprehensive Cancer Center, Northwestern Memorial Hospital, Chicago, Illinois
T-Cell Lymphomas

David S. Rosenthal MD
Professor of Medicine, Harvard Medical School; Co-Director, Leonard P. Zakim Center for Integrative Therapies, Dana-Farber Cancer Institute, Boston, Massachusetts; Director and Henry K. Oliver Professor of Hygiene, Harvard University, Cambridge, Massachusetts
Integrative Therapies in Patients With Hematologic Diseases

Rachel Rosovsky MD, MPH
Department of Medical Oncology, Massachusetts General Hospital, Boston, Massachusetts
Hematologic Manifestations of Systemic Disease: Renal Disease

Scott D. Rowley MD
Chief, Adult Blood and Marrow Transplantation Program, John Theurer Cancer Center, Hackensack University Medical Center, Hackensack, New Jersey
Practical Aspects of Hematologic Stem Cell Harvesting and Mobilization

Natalia Rydz MD
Hemostasis Fellow, Department of Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada
Structure, Biology, and Genetics of von Willebrand Factor

J. Evan Sadler MD, PhD
Professor and Director, Division of Hematology, Department of Medicine, Washington University School of Medicine, St. Louis, Missouri
Thrombotic Thrombocytopenic Purpura and the Hemolytic Uremic Syndrome

John T. Sandlund, Jr. MD
Department of Oncology, St. Jude Children's Research Hospital, University of Tennessee, Memphis, Tennessee
Malignant Lymphomas in Childhood

Steven Sauk MD, MS
Radiology Chief Resident, Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri
Mechanical Interventions in Arterial and Venous Thrombosis

Yogen Saunthararajah MB, BCh
Staff, Cleveland Clinic, Taussig Cancer Institute, Cleveland, Ohio; Associate Professor, University of Illinois at Chicago, Chicago, Illinois
Sickle Cell Disease: Clinical Features and Management

David Scadden MD
Gerald and Darlene Jordan Professor of Medicine; Co-Director, Harvard Stem Cell Institute; Co-Chair, Department of Stem Cell and Regenerative Biology, Harvard Medical School; Director, Center for Regenerative Medicine, Massachusetts General Hospital, Boston, Massachusetts
Hematopoietic Microenvironment

Kristen G. Schaefer MD
Instructor, Director of Medical Student and Resident Education, Adult Palliative Care Division, Department of Psychosocial Oncology and Palliative Care, Dana-Farber Cancer Institute, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts
Palliative Care

Fred J. Schiffman MD
Sigal Family Professor of Humanistic Medicine; Vice-Chair, Department of Medicine, Warren Alpert Medical School, Brown University, Providence, Rhode Island
The Spleen and Its Disorders

Alvin H. Schmaier MD
Robert W. Kellermeyer Professor of Hematology and Oncology, Departments of Medicine and Pathology, Case Western Reserve University, University Hospital Case Medical Center, Cleveland, Ohio
Laboratory Evaluation of Hemostatic and Thrombotic Disorders

Stanley L. Schrier MD
Professor of Medicine, Division of Hematology; Active Emeritus, Stanford University School of Medicine, Palo Alto, California
Red Blood Cell Enzymopathies
Extrinsic Nonimmune Hemolytic Anemias

Edward H. Schuchman PhD
Genetic Disease Foundation, Francis Crick Professor, Vice-Chairman for Research, Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York
Lysosomal Storage Diseases: Perspectives and Principles

Bridget Fowler Scullion PharmD, BCOP
Clinical Pharmacy Manager, Department of Pharmacy, Clinical Pharmacy Specialist, Palliative Care, Division of Adult Palliative Care, Department of Psychosocial Oncology and Palliative Care, Dana-Farber Cancer Institute, Boston, Massachusetts
Pain Management and Antiemetic Therapy in Hematologic Disorders

Kathy J. Selvaggi MD, MS
Director of Intensive Palliative Care Unit, Psychosocial Oncology and Palliative Care, Dana-Farber Cancer Institute; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Pain Management and Antiemetic Therapy in Hematologic Disorders

Montaser Shaheen MD
Assistant Professor, Department of Internal Medicine, Division of Hematology and Oncology, University of New Mexico School of Medicine, Albuquerque, New Mexico
Principles of Cytokine Signaling

Beth H. Shaz MD
Chief Medical Officer, New York Blood Center, New York, New York; Clinical Associate Professor, Department of Pathology and Laboratory Medicine, Emory University School of Medicine, Atlanta, Georgia
Human Blood Group Antigens and Antibodies
Principles of Plasma Transfusion: Plasma, Cryoprecipitate, Albumin, and Immunoglobulins

Andrea M. Sheehan MD
Assistant Professor, Department of Pathology and Immunology, Department of Pediatrics, Section of Hematology Oncology, Baylor College of Medicine, Houston, Texas
Resources for the Hematologist: Interpretive Comments and Selected Reference Values for Neonatal, Pediatric, and Adult Populations

Samuel A. Shelburne MD, PhD
Assistant Professor, Department of Infectious Diseases Infection Control and Employee Health, The University of Texas MD Anderson Cancer Center, Houston, Texas
Clinical Approach to Infections in the Compromised Host

Mark J. Shlomchik MD, PhD
Professor, Laboratory Medicine and Immunobiology, Yale University School of Medicine, New Haven, Connecticut
Tolerance and Autoimmunity

Susan B. Shurin MD
Acting Director, National Heart, Lung, and Blood Institute, Bethesda Maryland
The Spleen and Its Disorders

Leslie E. Silberstein MD
Director, Joint Program in Transfusion Medicine, Children's Hospital Boston; Director, Center for Human Cell Therapy, Boston, Massachusetts
Overview and Historical Perspective of Current Cell-Based Therapies
Preclinical Process of Cell-Based Therapies

Lev Silberstein MD, PhD
Instructor, Harvard Medical School, Center for Regenerative Medicine, Massachusetts General Hospital, Boston, Massachusetts
Hematopoietic Microenvironment

Roy L. Silverstein MD
John and Linda Mellowes Professor and Chair, Department of Medicine, Medical College of Wisconsin; Senior Scientist, Blood Research Institute of Blood Center of Wisconsin, Milwaukee, Wisconsin
Atherothrombosis

Steven R. Sloan MD, PhD
Director, Pediatric Transfusion Medicine, Joint Program in Transfusion Medicine, Department of Laboratory Medicine, Children's Hospital Boston, Boston, Massachusetts
Pediatric Transfusion Medicine

Franklin O. Smith MD
Marjory J. Johnson Endowed Chair and Professor of Pediatrics and Medicine, University of Cincinnati College of Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Myelodysplastic and Myeloproliferative Neoplasms in Children

James Smith BSc
McMaster University, Hamilton, Ontario, Canada
Diseases of Platelet Number: Immune Thrombocytopenia, Neonatal Alloimmune Thrombocytopenia, and Posttransfusion Purpura

Edward L. Snyder MD
Professor, Department of Laboratory Medicine, Yale University School of Medicine, New Haven, Connecticut
Transfusion Reactions to Blood and Cell Therapy Products

Gerald A. Soff MD
Director, Benign Hematology Program, Memorial Sloan-Kettering Cancer Center, New York, New York
Hematologic Manifestations of Cancer

PREFACE

Welcome to the sixth edition of *Hematology: Basic Principles and Practice*. This book has evolved over the past 2.5 decades and represents the collective efforts of the editorial team, which has focused on this book being informative, user friendly, and scholarly. The central hypothesis driving each edition remains unchanged—our belief that up-to-date knowledge of the ever-evolving science of hematology is essential to provide superior care to patients with blood disorders and that high-quality bench research into the pathogenesis of these disorders depends on an intimate understanding of the clinical manifestations of these diseases.

To meet these lofty ambitions, the educational team has continued to evolve. Three editors from the previous edition, Drs. Bruce Furie, Sanford J. Shattil, and Phillip G. McGlave, elected not to participate in this edition. The Editorial Board owes each of these individuals a debt of gratitude. Bruce and Sandy served as editors of the sections dealing with thrombosis and hemostasis for each of the previous five editions. Phil created the section on stem cell transplantation. The efforts and vision of each of these individuals have clearly been an important source of strength for this book. Dr. Jeffrey I. Weitz is the new editor for the sections dealing with thrombosis and hemostasis. Jeff is a professor of medicine and biochemistry at McMaster University and executive director of the Thrombosis and Atherosclerosis Research Institute in Hamilton, Ontario. He also holds the Canada Research Chair (Tier 1) in thrombosis as well as the Heart and Stroke Foundation of Ontario-Fraser Mustard Chair in Cardiovascular Research. He has modified the sections on thrombosis and hemostasis to meet the challenges encountered by clinicians and research scientists in 2013 while maintaining the high standards set by Drs. Shattil and Furie.

Dr. Helen Heslop from the Baylor College of Medicine has expanded her efforts in this edition. She has refocused and edited the section dealing with stem cell transplantation. Helen is intimately involved in efforts in both clinical and experimental stem cell transplantation and is uniquely suited to enhance the platform created by Dr. McGlave.

Dr. John Anastasi from the University of Chicago is now a full member of our editorial team. During development of the previous edition, he assisted in selecting images for many of the chapters, but he now plays a much larger role, enhancing the hematopathology sections of the numerous chapters dealing with cellular aspects of hematology.

During the past decades, medical publishing has undergone revolutionary changes, which have become possible with the increased availability and access to the Internet. In the sixth edition, *Hematology: Basic Principles and Practice* has capitalized on this new format. Although a print edition of the book will continue to be available, we expect that a growing number of readers will use the electronic version. We hope that the availability of these two formats will meet the needs of every reader and provide them with the desired information in a fashion with which they are most comfortable. To keep the edition updated, supplemental information will be provided through Internet access so that readers can remain informed.

Each one of us continues to enjoy the challenges that we have encountered in preparing this comprehensive textbook for our readership. We hope that this new edition continues to meet the expectations and growing needs of our readership.

CHAPTER 1

ANATOMY AND PHYSIOLOGY OF THE GENE

Andrew J. Wagner, Nancy Berliner, and Edward J. Benz, Jr.

Normal blood cells have limited life spans; they must be replenished in precise numbers by a continuously renewing population of progenitor cells. Homeostasis of the blood requires that proliferation of these cells be efficient yet strictly constrained. Many distinctive types of mature blood cells must arise from these progenitors by a controlled process of commitment to, and execution of, complex programs of differentiation. Thus, developing red blood cells must produce large quantities of hemoglobin but not the myeloperoxidase characteristic of granulocytes, the immunoglobulins characteristic of lymphocytes, or the fibrinogen receptors characteristic of platelets. Similarly, the maintenance of normal amounts of coagulant and anticoagulant proteins in the circulation requires exquisitely regulated production, destruction, and interaction of the components. Understanding the basic biologic principles underlying cell growth, differentiation, and protein biosynthesis requires a thorough knowledge of the structure and regulated expression of genes because the gene is now known to be the fundamental unit by which biologic information is stored, transmitted, and expressed in a regulated fashion.

Genes were originally characterized as mathematical units of inheritance. They are now known to consist of molecules of deoxyribonucleic acid (DNA). By virtue of their ability to store information in the form of nucleotide sequences, to transmit it by means of semiconservative replication to daughter cells during mitosis and meiosis, and to express it by directing the incorporation of amino acids into proteins, DNA molecules are the chemical transducers of genetic information flow. Efforts to understand the biochemical means by which this transduction is accomplished have given rise to the discipline of molecular genetics.

THE GENETIC VIEW OF THE BIOSPHERE: THE CENTRAL DOGMA OF MOLECULAR BIOLOGY

The fundamental premise of the molecular biologist is that the magnificent diversity encountered in nature is ultimately governed by genes. The capacity of genes to exert this control is in turn determined by relatively simple stereochemical rules, first appreciated by Watson and Crick in the 1950s. These rules constrain the types of interactions that can occur between two molecules of DNA or ribonucleic acid (RNA).

DNA and RNA are linear polymers consisting of four types of nucleotide subunits. Proteins are linear unbranched polymers consisting of 21 types of amino acid subunits. Each amino acid is distinguished from the others by the chemical nature of its side chain, the moiety not involved in forming the peptide bond links of the chain. The properties of cells, tissues, and organisms depend largely on the aggregate structures and properties of their proteins. The central dogma of molecular biology states that genes control these properties by controlling the structures of proteins, the timing and amount of their production, and the coordination of their synthesis with that of other proteins. The information needed to achieve these ends is transmitted by a class of nucleic acid molecules called RNA. Genetic information thus flows in the direction DNA → RNA → protein. This central dogma provides, in principle, a universal approach for investigating the biologic properties and behavior of any given cell, tissue, or organism by study of the controlling genes. Methods permitting direct manipulation of DNA sequences should then be universally applicable to the study of all living entities. Indeed, the power of the molecular genetic approach lies in the universality of its utility.

One exception to the central dogma of molecular biology that is especially relevant to hematologists is the storage of genetic information in RNA molecules in certain viruses, notably the retroviruses associated with T-cell leukemia and lymphoma and the human immunodeficiency virus. When retroviruses enter the cell, the RNA genome is copied into a DNA replica by an enzyme called *reverse transcriptase*. This DNA representation of the viral genome is then expressed according to the rules of the central dogma. Retroviruses thus represent a variation on the theme rather than a true exception to or violation of the rules.

ANATOMY AND PHYSIOLOGY OF GENES

DNA Structure

DNA molecules are extremely long, unbranched polymers of nucleotide subunits. Each nucleotide contains a sugar moiety called deoxyribose, a phosphate group attached to the 5′ carbon position, and a purine or pyrimidine base attached to the 1′ position (Fig. 1-1). The linkages in the chain are formed by phosphodiester bonds between the 5′ position of each sugar residue and the 3′ position of the adjacent residue in the chain (see Fig. 1-1). The sugar phosphate links form the backbone of the polymer, from which the purine or pyrimidine bases project perpendicularly.

The haploid human genome consists of 23 long, double-stranded DNA molecules tightly complexed with histones and other nuclear proteins to form compact linear structures called *chromosomes*. The genome contains 3 billion nucleotides; each chromosome is thus 50 to 200 million bases in length. The individual genes are aligned along each chromosome. The human genome contains about 30,000 genes. Blood cells, similar to most somatic cells, are diploid. That is, each chromosome is present in two copies, so there are 46 chromosomes consisting of approximately 6 billion base pairs (bp) of DNA.

The four nucleotide bases in DNA are the purines (adenosine and guanosine) and the pyrimidines (thymine and cytosine). The basic chemical configuration of the other nucleic acid found in cells, RNA, is quite similar except that the sugar is ribose (having a hydroxyl group attached to the 2′ carbon rather than the hydrogen found in deoxyribose) and the pyrimidine base uracil is used in place of thymine. The bases are commonly referred to by a shorthand notation: the letters A, C, T, G, and U are used to refer to adenosine, cytosine, thymine, guanosine, and uracil, respectively.

The ends of DNA and RNA strands are chemically distinct because of the 3′ → 5′ phosphodiester bond linkage that ties adjacent bases together (see Fig. 1-1). One end of the strand (the 3′ end) has an unlinked (free at the 3′ carbon) sugar position and the other (the 5′ end) has a free 5′ position. There is thus a polarity to the sequence of bases in a DNA strand: the same sequence of bases read in a 3′ → 5′ direction carries a different meaning than if read in a 5′ → 3′ direction. Cellular enzymes can thus distinguish one end of a

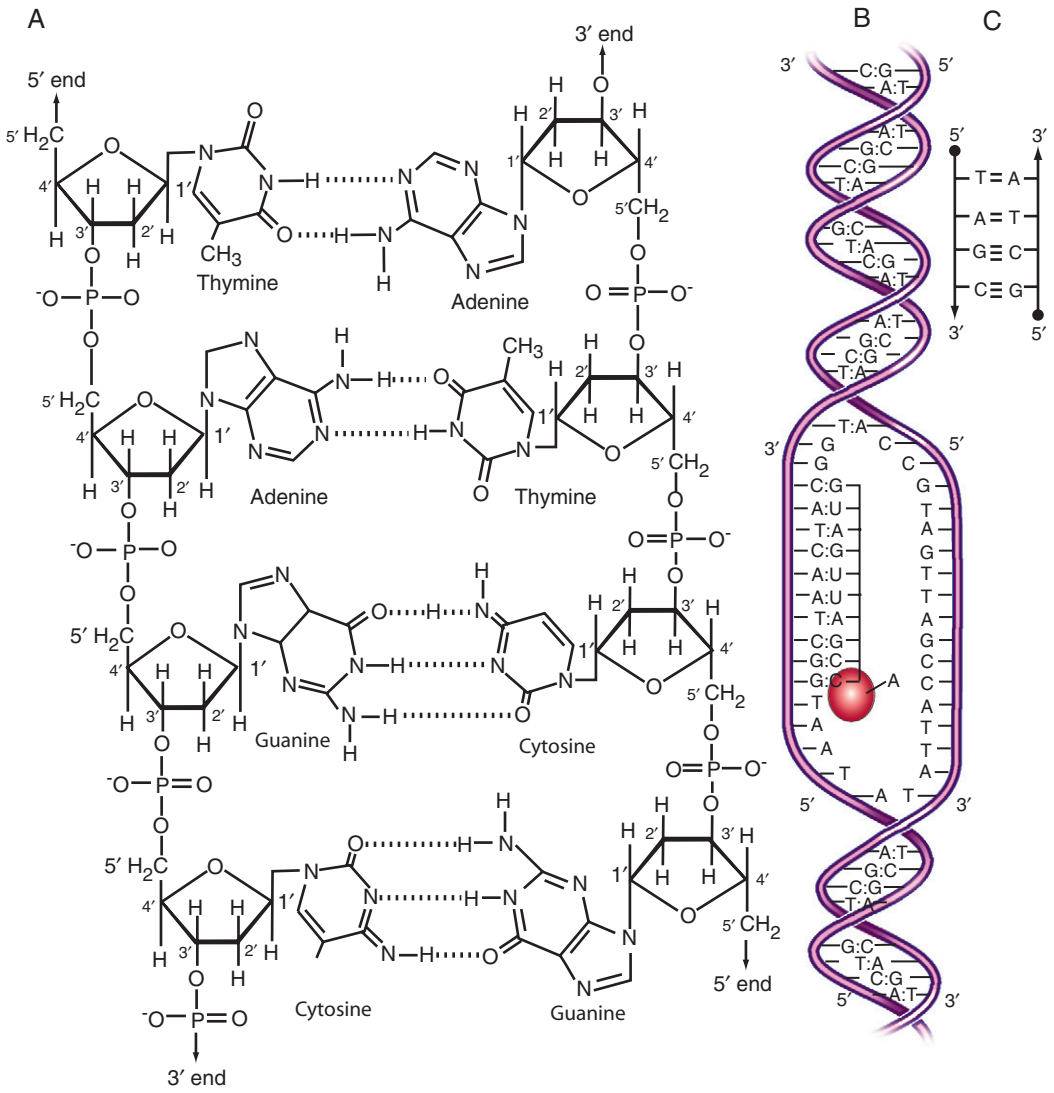

Figure 1-1 STRUCTURE, BASE PAIRING, POLARITY, AND TEMPLATE PROPERTIES OF DNA. **A,** Structures of the four nitrogenous bases projecting from sugar phosphate backbones. The hydrogen bonds between them form base pairs holding complementary strands of DNA together. Note that whereas A–T and T–A base pairs have only two hydrogen bonds, C–G and G–C pairs have three. **B,** The double helical structure of DNA results from base pairing of strands to form a double-stranded molecule with the backbones on the outside and the hydrogen-bonded bases stacked in the middle. Also shown schematically is the separation (unwinding) of a region of the helix by mRNA polymerase, which is shown using one of the strands as a template for the synthesis of an mRNA precursor molecule. Note that new bases added to the growing RNA strand obey the rules of Watson-Crick base pairing (see text). Uracil (U) in RNA replaces T in DNA and, like T, forms base pairs with A. **C,** Diagram of the antiparallel nature of the strands, based on the stereochemical 3′ → 5′ polarity of the strands. The chemical differences between reading along the backbone in the 5′ → 3′ and 3′ → 5′ directions can be appreciated by reference to part **A.** *A,* Adenosine; *C,* cytosine; *G,* guanosine; *T,* thymine.

nucleic acid from the other; most enzymes that "read" the DNA sequence tend to do so only in one direction (3′ → 5′ or 5′ → 3′ but not both). Most nucleic acid–synthesizing enzymes, for instance, add new bases to the strand in a 5′ → 3′ direction.

The ability of DNA molecules to store information resides in the sequence of nucleotide bases arrayed along the polymer chain. Under the physiologic conditions in living cells, DNA is thermodynamically most stable when two strands coil around each other to form a double-stranded helix. The strands are aligned in an "antiparallel" direction, having opposite 3′ → 5′ polarity (see Fig. 1-1). The DNA strands are held together by hydrogen bonds between the bases on one strand and the bases on the opposite (complementary) strand. The stereochemistry of these interactions allows bonds to form between the two strands only when adenine on one strand pairs with thymine at the same position of the opposite strand, or guanine with cytosine—the Watson-Crick rules of base pairing. Two strands joined together in compliance with these rules are said to have "complementary" base sequences.

These thermodynamic rules imply that the sequence of bases along one DNA strand immediately dictates the sequence of bases that must be present along the complementary strand in the double helix. For example, whenever an A occurs along one strand, a T must be present at that exact position on the opposite strand; a G must always be paired with a C, a T with an A, and a C with a G. In RNA–RNA or RNA–DNA double-stranded molecules, U–A base pairs replace T–A pairs.

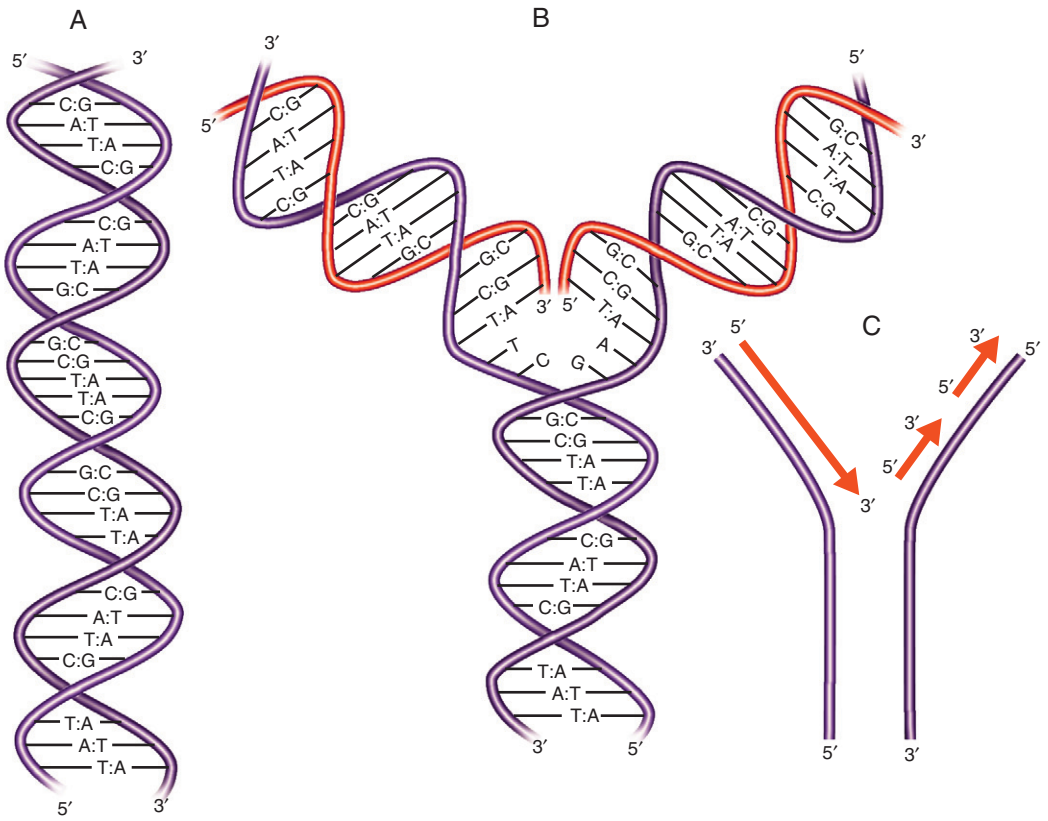

Figure 1-2 SEMICONSERVATIVE REPLICATION OF DNA. **A,** The process by which the DNA molecule on the left is replicated into two daughter molecules, as occurs during cell division. Replication occurs by separation of the parent molecule into the single-stranded form at one end, reading of each of the daughter strands in the 3′ → 5′ direction by DNA polymerase, and addition of new bases to growing daughter strands in the 5′ → 3′ direction. **B,** The replicated portions of the daughter molecules are identical to each other *(red)*. Each carries one of the two strands of the parent molecule, accounting for the term *semiconservative replication.* Note the presence of the replication fork, the point at which the parent DNA is being unwound. **C,** The antiparallel nature of the DNA strands demands that replication proceed toward the fork in one direction and away from the fork in the other *(red)*. This means that replication is actually accomplished by reading of short stretches of DNA followed by ligation of the short daughter strand regions to form an intact daughter strand.

STORAGE AND TRANSMISSION OF GENETIC INFORMATION

The rules of Watson-Crick base pairing apply to DNA–RNA, RNA–RNA, and DNA–DNA double-stranded molecules. Enzymes that replicate or polymerize DNA and RNA molecules obey the base-pairing rules. By using an existing strand of DNA or RNA as the template, a new (daughter) strand is copied (transcribed) by reading processively along the base sequence of the template strand, adding to the growing strand at each position only that base that is complementary to the corresponding base in the template according to the Watson-Crick rules. Thus, a DNA strand having the base sequence 5′-GCTATG-3′ could be copied by DNA polymerase only into a daughter strand having the sequence 3′-CGATAC-5′. Note that the sequence of the template strand provides all the information needed to predict the nucleotide sequence of the complementary daughter strand. Genetic information is thus stored in the form of base-paired nucleotide sequences.

If a double-stranded DNA molecule is separated into its two component strands and each strand is then used as a template to synthesize a new daughter strand, the product will be two double-stranded daughter DNA molecules, each identical to the original parent molecule. This semiconservative replication process is exactly what occurs during mitosis and meiosis as cell division proceeds (Fig. 1-2). The rules of Watson-Crick base pairing thus provide for the faithful transmission of exact copies of the cellular genome to subsequent generations.

EXPRESSION OF GENETIC INFORMATION THROUGH THE GENETIC CODE AND PROTEIN SYNTHESIS

The information stored in the DNA base sequence achieves its impact on the structure, function, and behavior of organisms by governing the structures, timing, and amounts of protein synthesized in the cells. The primary structure (i.e., the amino acid sequence) of each protein determines its three-dimensional conformation and therefore properties (e.g., shape, enzymatic activity, ability to interact with other molecules, stability). In the aggregate, these proteins control cell structure and metabolism. The process by which DNA achieves its control of cells through protein synthesis is called *gene expression*.

An outline of the basic pathway of gene expression in eukaryotic cells is shown in Fig. 1-3. The DNA base sequence is first copied into an RNA molecule, called *premessenger RNA,* by messenger RNA (mRNA) polymerase. Premessenger RNA has a base sequence identical to the DNA coding strand. Genes in eukaryotic species consist of tandem arrays of sequences encoding mRNA (exons); these sequences alternate with sequences (introns) present in the initial mRNA

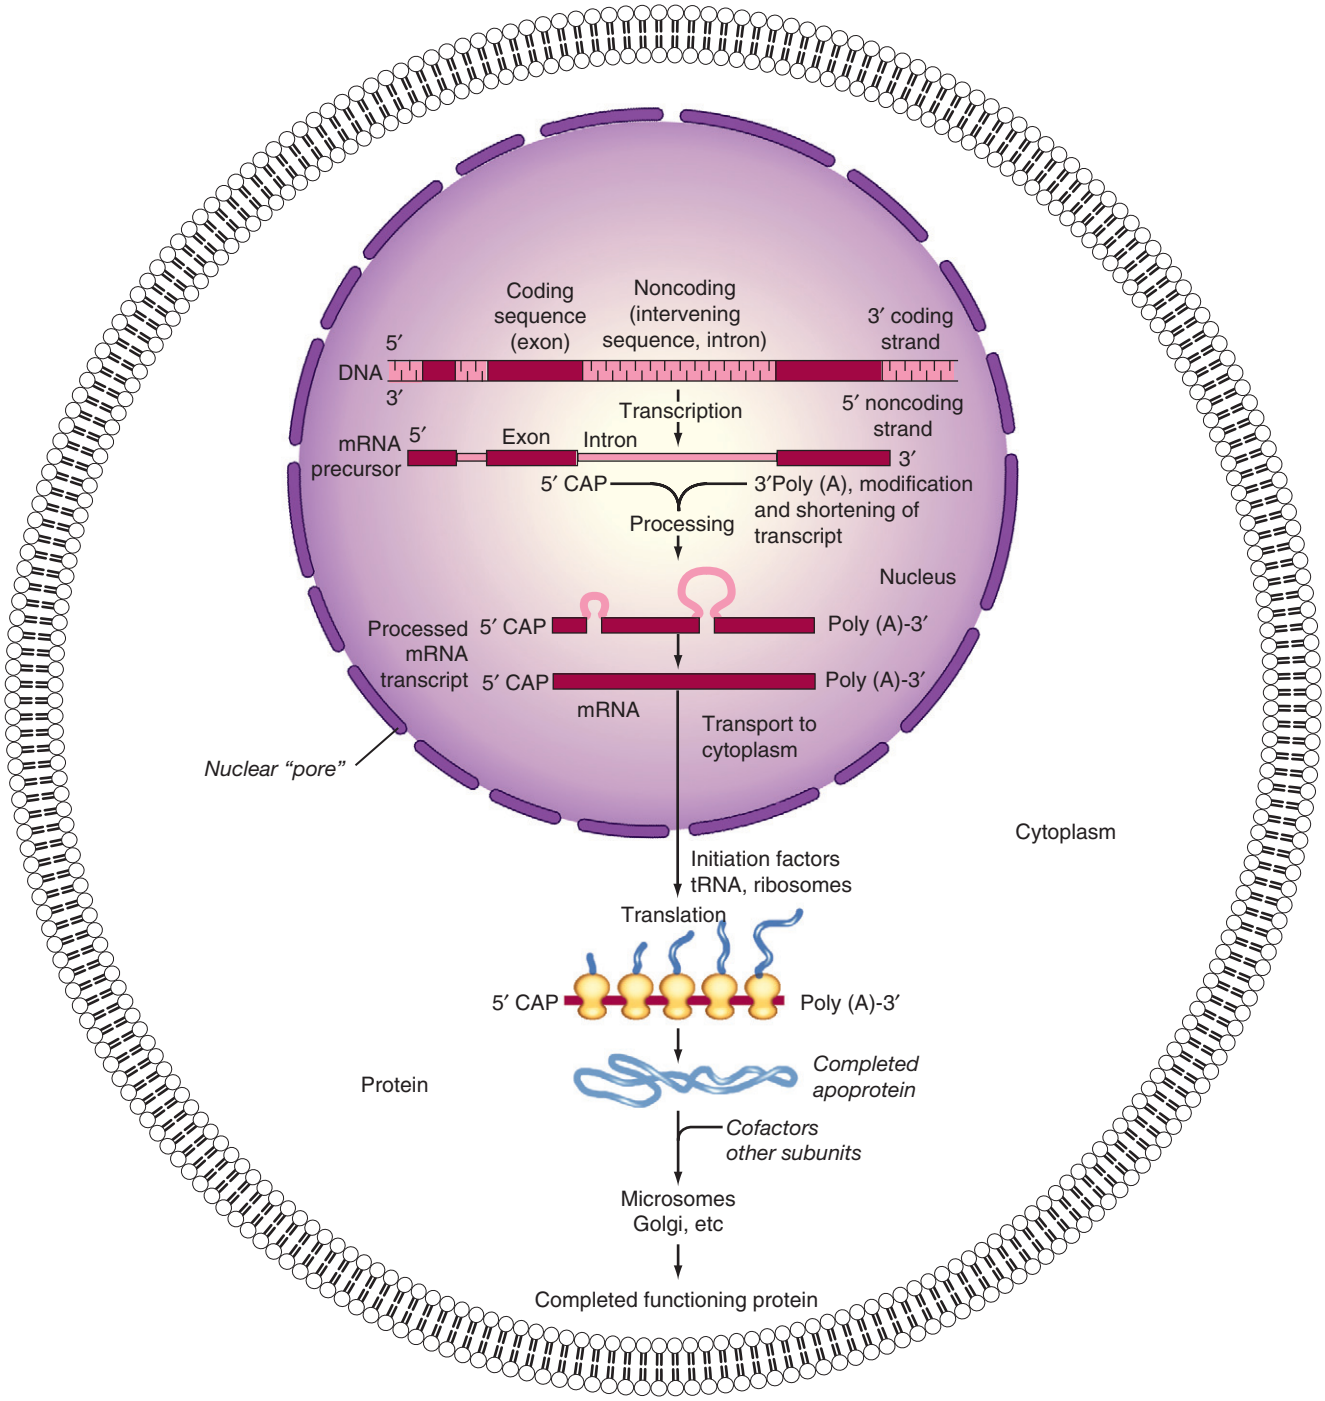

Figure 1-3 SYNTHESIS OF mRNA AND PROTEIN—THE PATHWAY OF GENE EXPRESSION. The diagram of the DNA gene shows the alternating array of exons *(red)* and introns *(shaded color)* typical of most eukaryotic genes. Transcription of the mRNA precursor, addition of the 5′-CAP and 3′-poly (A) tail, splicing and excision of introns, transport to the cytoplasm through the nuclear pores, translation into the amino acid sequence of the apoprotein, and posttranslational processing of the protein are described in the text. Translation proceeds from the initiator methionine codon near the 5′ end of the mRNA, with incorporation of the amino terminal end of the protein. As the mRNA is read in a 5′ → 3′ direction, the nascent polypeptide is assembled in an amino → carboxyl terminal direction.

transcript (premessenger RNA) but absent from the mature mRNA. The entire gene is transcribed into the large precursor, which is then further processed (spliced) in the nucleus. The introns are excised from the final mature mRNA molecule, which is then exported to the cytoplasm to be decoded (translated) into the amino acid sequence of the protein by association with a biochemically complex group of ribonucleoprotein structures called *ribosomes*. Ribosomes contain two subunits: the 60S subunit contains a single, large (28S) ribosomal RNA molecule complexed with multiple proteins, and the RNA component of the 40S subunit is a smaller (18S) ribosomal RNA molecule.

Ribosomes read mRNA sequence in a ticker tape fashion three bases at a time, inserting the appropriate amino acid encoded by each three-base code word or codon into the appropriate position of the growing protein chain. This process is called *mRNA translation*. The glossary used by cells to know which amino acids are encoded by each

DNA codon is called the *genetic code* (Table 1-1). Each amino acid is encoded by a sequence of three successive bases. Because there are four code letters (A, C, G, and U) and because sequences read in the 5′ → 3′ direction have a different biologic meaning than sequences read in the 3′ → 5′ direction, there are 4^3, or 64, possible codons consisting of three bases.

There are 21 naturally occurring amino acids found in proteins. Thus, more codons are available than amino acids to be encoded. As noted in Table 1-1, a consequence of this redundancy is that some amino acids are encoded by more than one codon. For example, six distinct codons can specify incorporation of arginine into a growing amino acid chain, four codons can specify valine, two can specify glutamic acid, and only one each methionine or tryptophan. In no case does a single codon encode more than one amino acid. Codons thus predict unambiguously the amino acid sequence they encode. However, one cannot easily read backward from the amino acid sequence to decipher the *exact* encoding DNA sequence. These facts are summarized by saying that the code is degenerate but not ambiguous.

Table 1-1 The Genetic Code* Messenger RNA Codons for the Amino Acids

Alanine	Arginine	Asparagine	Aspartic Acid	Cysteine

UAG				
UGA				

*Note that most of the degeneracy in the code is in the third base position (e.g., lysine, AA[G or C]; asparagine, AA[C or U]; valine GUN [where N is any base]).
†AUG is also used as the chain-initiation codon when surrounded by the Kozak consensus sequence.
‡Hydroxyproline, the 21st amino acid, is generated by posttranslational modification of proline. It is almost exclusively confined to collagen subunits.
§The codons that signal the end of translation, also called nonsense or termination codons, are described by their nicknames *amber* (UAG), *ochre* (UAA), and *opal* (UGA).

Some specialized codons serve as punctuation points during translation. The methionine codon (AUG), when surrounded by a consensus sequence (the Kozak box) near the beginning (5′ end) of the mRNA, serves as the initiator codon signaling the first amino acid to be incorporated. All proteins thus begin with a methionine residue, but this is often removed later in the translational process. Three codons, UAG, UAA, and UGA, serve as translation terminators, signaling the end of translation.

The adaptor molecules mediating individual decoding events during mRNA translation are small (40 bases long) RNA molecules called *transfer RNAs* (tRNAs). When bound into a ribosome, each tRNA exposes a three-base segment within its sequence called the *anticodon*. These three bases attempt to pair with the three-base codon exposed on the mRNA. If the anticodon is complementary in sequence to the codon, a stable interaction among the mRNA, the ribosome, and the tRNA molecule results. Each tRNA also contains a separate region that is adapted for covalent binding to an amino acid. The enzymes that catalyze the binding of each amino acid are constrained in such a way that each tRNA species can bind only to a single amino acid. For example, tRNA molecules containing the anticodon 3′-AAA-5′, which is complementary to a 5′-UUU-3′ (phenylalanine) codon in mRNA, can only be bound to or charged with phenylalanine; tRNA containing the anticodon 3′-UAG-5′ can only be charged with isoleucine, and so forth.

Transfer RNAs and their amino acyl tRNA synthetases provide for the coupling of nucleic acid information to protein information needed to convert the genetic code to an amino acid sequence. Ribosomes provide the structural matrix on which tRNA anticodons and mRNA codons become properly exposed and aligned in an orderly, linear, and sequential fashion. As each new codon is exposed, the appropriate charged tRNA species is bound. A peptide bond is then formed between the amino acid carried by this tRNA and the C-terminal residue on the existing nascent protein chain. The growing chain is transferred to the new tRNA in the process, so that it is held in place as the next tRNA is brought in. This cycle is repeated until completion of translation. The completed polypeptide chain is then transferred to other organelles for further processing (e.g., to the endoplasmic reticulum and the Golgi apparatus) or released into cytosol for association of the newly completed chain with other subunits to form complex multimeric proteins (e.g., hemoglobin) and so forth, as discussed in Chapter 3.

mRNA METABOLISM

In eukaryotic cells, mRNA is initially synthesized in the nucleus (see Figs. 1-3 and 1-4). Before the initial transcript becomes suitable for translation in the cytoplasm, mRNA processing and transport occur by a complex series of events including excision of the portions of the mRNA corresponding to the introns of the gene (mRNA splicing), modification of the 5′ and 3′ ends of the mRNA to render them more stable and translatable, and transport to the cytoplasm. Moreover, the amount of any particular mRNA moiety in both prokaryotic and eukaryotic cells is governed not only by the composite rate of mRNA synthesis (transcription, processing, and transport) but also by its degradation by cytoplasmic ribonucleases (RNA degradation). Many mRNA species of special importance in hematology (e.g., mRNAs for growth factors and their receptors, proto-oncogene mRNAs, acute-phase reactants) are exquisitely regulated by control of their stability (half-life) in the cytoplasm.

Posttranscriptional mRNA metabolism is complex. Only a few relevant details are considered in this section.

mRNA Splicing

The initial transcript of eukaryotic genes contains several subregions (see Fig. 1-4). Most striking is the tandem alignment of exons and introns. Precise excision of intron sequences and ligation of exons is critical for production of mature mRNA. This process is called

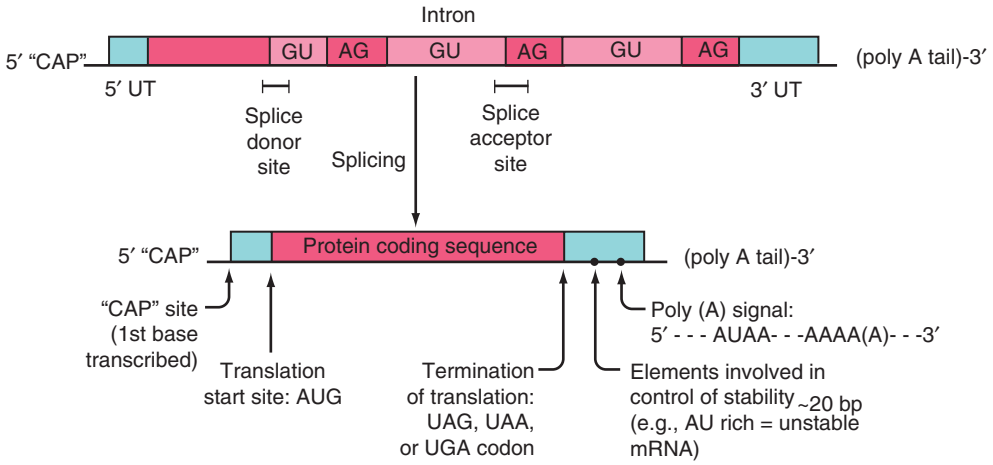

Figure 1-4 ANATOMY OF THE PRODUCTS OF THE STRUCTURAL GENE (mRNA PRECURSOR AND mRNA). This schematic shows the configuration of the critical anatomic elements of an mRNA precursor, which represents the primary copy of the structural portion of the gene. The sequences GU and AG indicate, respectively, the invariant dinucleotides present in the donor and acceptor sites at which introns are spliced out of the precursor. Not shown are the less stringently conserved consensus sequences that must precede and succeed each of these sites for a short distance.

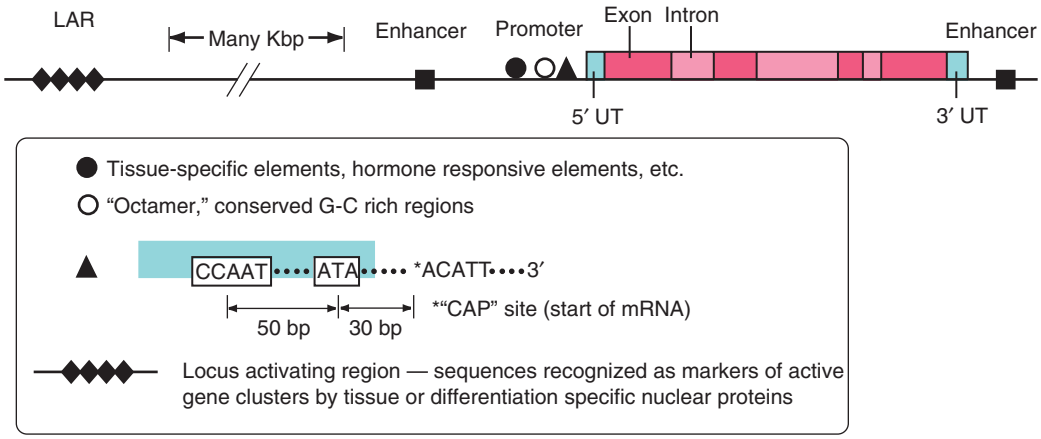

Figure 1-5 Regulatory elements flanking the structural gene.

mRNA splicing, and it occurs on complexes of small nuclear RNAs and proteins called snRNPs; the term *spliceosome* is also used to describe the intranuclear organelle that mediates mRNA splicing reactions. The biochemical mechanism for splicing is complex. A consensus sequence, which includes the dinucleotide GU, is recognized as the donor site at the 5′ end of the intron (5′ end refers to the polarity of the mRNA strand coding for protein); a second consensus sequence ending in the dinucleotide AG is recognized as the acceptor site, which marks the distal end of the intron (see Figs. 1-4 and 1-5). The spliceosome recognizes the donor and acceptor and forms an intermediate lariat structure that provides for both excision of the intron and proper alignment of the cut ends of the two exons for ligation in precise register.

Messenger RNA splicing has proved to be an important mechanism for greatly increasing the versatility and diversity of expression of a single gene. For example, some genes contain an array of more exons than are actually found in any mature mRNA species encoded by that gene. Several different mRNA and protein products can arise from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA products. This phenomenon is called *alternative mRNA splicing*. It permits a single gene to code for multiple mRNA and protein products with related but distinct structures and functions. The mechanisms by which individual exons are selected or rejected remain obscure. For present purposes, it is sufficient to note that important physiologic changes in cells can be regulated by altering the patterns of mRNA splicing products arising from single genes.

Many inherited hematologic diseases arise from mutations that derange mRNA splicing. For example, some of the most common forms of the thalassemia syndromes and hemophilia arise by mutations that alter normal splicing signals or create splicing signals where they normally do not exist (activation of cryptic splice sites).

Modification of the Ends of the mRNA Molecule

Most eukaryotic mRNA species are polyadenylated at their 3′ ends. mRNA precursors are initially synthesized as large molecules that extend farther downstream from the 3′ end of the mature mRNA molecule. Polyadenylation results in the addition of stretches of 100 to 150 A residues at the 3′ end. Such an addition is often called the *poly-A tail* and is of variable length. Polyadenylation facilitates rapid early cleavage of the unwanted 3′ sequences from the transcript and is also important for stability or transport of the mRNA out of the

nucleus. Signals near the 3′ extremity of the mature mRNA mark positions at which polyadenylation occurs. The consensus signal is AUAAA (see Fig. 1-4).

Mutations in the poly-A signal sequence have been shown to cause thalassemia.

At the 5′ end of the mRNA, a complex oligonucleotide having unusual phosphodiester bonds is added. This structure contains the nucleotide 7-methyl-guanosine and is called *CAP* (see Fig. 1-4). The 5′-CAP enhances both mRNA stability and the ability of the mRNA to interact with protein translation factors and ribosomes.

5′ and 3′ Untranslated Sequences

The 5′ and 3′ extremities of mRNA extend beyond the initiator and terminator codons that mark the beginning and the end of the sequences actually translated into proteins (see Figs. 1-4 and 1-5). These so-called 5′ and 3′ untranslated regions (5′ UTR and 3′ UTR) are involved in determining mRNA stability and the efficiency with which mRNA species can be translated. For example, if the 3′ UTR of a very stable mRNA (e.g., globin mRNA) is swapped with the 3′ UTR of a highly unstable mRNA (e.g., the c-myc proto-oncogene), the c-myc mRNA becomes more stable. Conversely, attachment of the 3′ UTR of c-myc to a globin molecule renders it unstable. Instability is often associated with repeated sequences rich in A and U in the 3′ UTR (see Fig. 1-4). Similarly, the UTRs in mRNAs coding for proteins involved in iron metabolism mediate altered mRNA stability or translatability by binding iron-laden proteins.

Transport of mRNA from Nucleus to Cytoplasm: mRNP Particles

An additional potential step for regulation or disruption of mRNA metabolism occurs during the transport from nucleus to cytoplasm. mRNA transport is an active, energy-consuming process. Moreover, at least some mRNAs appear to enter the cytoplasm in the form of complexes bound to proteins (mRNPs). mRNPs may regulate stability of the mRNAs and their access to translational apparatus. Some evidence indicates that certain mRNPs are present in the cytoplasm but are not translated (masked message) until proper physiologic signals are received.

GENE REGULATION

Virtually all cells of an organism receive a complete copy of the DNA genome inherited at the time of conception. The panoply of distinct cell types and tissues found in any complex organism is possible only because different portions of the genome are selectively expressed or repressed in each cell type. Each cell must "know" which genes to express, how actively to express them, and when to express them. This biologic necessity has come to be known as *gene regulation* or *regulated gene expression*. Understanding gene regulation provides insight into how pluripotent stem cells determine that they will express the proper sets of genes in daughter progenitor cells that differentiate along each lineage. Major hematologic disorders (e.g., the leukemias and lymphomas), immunodeficiency states, and myeloproliferative syndromes result from derangements in the system of gene regulation. An understanding of the ways that genes are selected for expression thus remains one of the major frontiers of biology and medicine.

EPIGENETIC REGULATION OF GENE EXPRESSION

Most of the DNA in living cells is inactivated by formation of a nucleoprotein complex called *chromatin*. The histone and nonhistone proteins in chromatin effectively sequester genes from enzymes needed for expression. The most tightly compacted chromatin regions are called *euchromatin*. Heterochromatin, less tightly packed, contains actively transcribed genes. Activation of a gene for expression (i.e., transcription) requires that it become less compacted and more accessible to the transcription apparatus. These processes involve both cis-acting and trans-acting factors. Cis-acting elements are regulatory DNA sequences within or flanking the genes. They are recognized by trans-acting factors, which are nuclear DNA–binding proteins needed for transcriptional regulation.

DNA sequence regions flanking genes are called *cis*-acting because they influence expression of nearby genes only on the same chromosome. These sequences do not usually encode mRNA or protein molecules. They alter the conformation of the gene within chromatin in such a way as to facilitate or inhibit access to the factors that modulate transcription. These interactions may twist or kink the DNA in such a way as to control exposure to other molecules. When exogenous nucleases are added in small amounts to nuclei, these exposed sequence regions become especially sensitive to the DNA-cutting action of the nucleases. Thus, nuclease-hypersensitive sites in DNA have come to be appreciated as markers for regions in or near genes that are interacting with regulatory nuclear proteins.

Methylation is another structural feature that can be used to recognize differences between actively transcribed and inactive genes. Most eukaryotic DNA is heavily methylated, that is, the DNA is modified by the addition of a methyl group to the 5 position of the cytosine pyrimidine ring (5-methyl-C). In general, whereas heavily methylated genes are inactive, active genes are relatively hypomethylated, especially in the 5′ flanking regions containing the promoter and other regulatory elements (see "Enhancers, Promoters, and Silencers"). These flanking regions frequently include DNA sequences with a high content of Cs and Gs (CpG islands). Hypomethylated CpG islands (detectable by methylation-sensitive restriction endonucleases) serve as markers of actively transcribed genes. For example, a search for undermethylated CpG islands on chromosome 7 facilitated the search for the gene for cystic fibrosis.

DNA methylation is facilitated by DNA methyltransferases. DNA replication incorporates unmethylated nucleotides into each nascent strand, thus leading to demethylated DNA. For cytosines to become methylated, the methyltransferases must act after each round of replication. After an initial wave of demethylation early in embryonic development, regulatory areas are methylated during various stages of development and differentiation. Aberrant DNA methylation also occurs as an early step during tumorigenesis, leading to silencing of tumor suppressor genes and of genes related to differentiation. This finding has led to induction of DNA demethylation as a target in cancer therapy. Indeed, 5-azacytidine, a cytidine analog unable to be methylated, and the related compound decitabine, are approved by the United States Food and Drug Administration for use in myelodysplastic syndromes, and their use in cases of other malignancies is being investigated.

Although it is poorly understood how particular regions of DNA are targeted for methylation, it is becoming increasingly apparent that this modification targets further alterations in chromatin proteins that in turn influence gene expression. Histone acetylation, phosphorylation, and methylation of the *N*-terminal tail are currently the focus of intense study. Acetylation of lysine residues (catalyzed by histone acetyltransferases), for example, is associated with transcriptional activation. Conversely, histone deacetylation (catalyzed by histone deacetylase) leads to gene silencing. Histone deacetylases are recruited to areas of DNA methylation by DNA methyltransferases and by methyl–DNA-binding proteins, thus linking DNA methylation to histone deacetylation. Drugs inhibiting these enzymes are being studied as anticancer agents.

The regulation of histone acetylation and deacetylation appears to be linked to gene expression, but the roles of histone phosphorylation and methylation are less well understood. Current research suggests that in addition to gene regulation, histone modifications contribute to the "epigenetic code" and are thus a means by which information regarding chromatin structure is passed to daughter cells after DNA replication occurs.

ENHANCERS, PROMOTERS, AND SILENCERS

Several types of cis-active DNA sequence elements have been defined according to the presumed consequences of their interaction with nuclear proteins (see Fig. 1-5). Promoters are found just upstream (to the 5′ side) of the start of mRNA transcription (the CAP). mRNA polymerases appear to bind first to the promoter region and thereby gain access to the structural gene sequences downstream. Promoters thus serve a dual function of being binding sites for mRNA polymerase and marking for the polymerase the downstream point at which transcription should start.

Enhancers are more complicated DNA sequence elements. Enhancers can lie on either side of a gene or even within the gene. Enhancers bind transcription factors and thereby stimulate expression of genes nearby. The domain of influence of enhancers (i.e., the number of genes to either side whose expression is stimulated) varies. Some enhancers influence only the adjacent gene; others seem to mark the boundaries of large multigene clusters (gene domains) whose coordinated expression is appropriate to a particular tissue type or a particular time. For example, the very high levels of globin gene expression in erythroid cells depend on the function of an enhancer that seems to activate the entire gene cluster and is thus called a *locus-activating region* (see Fig. 1-5). The nuclear factors interacting with enhancers are probably induced into synthesis or activation as part of the process of differentiation. Chromosomal rearrangements that place a gene that is usually tightly regulated under the control of a highly active enhancer can lead to overexpression of that gene. This commonly occurs in Burkitt lymphoma, for example, in which the MYC proto-oncogene is juxtaposed and dysregulated by an immunoglobulin enhancer.

Silencer sequences serve a function that is the obverse of enhancers. When bound by the appropriate nuclear proteins, silencer sequences cause repression of gene expression. Some evidence indicates that the same sequence elements can act as enhancers or silencers under different conditions, presumably by being bound by different sets of proteins having opposite effects on transcription. *Insulators* are sequence domains that mark the "boundaries" of multigene clusters, thereby preventing activation of one set of genes from "leaking" into nearby genes.

TRANSCRIPTION FACTORS

Transcription factors are nuclear proteins that exhibit gene-specific DNA binding. Considerable information is now available about these nuclear proteins and their biochemical properties, but their physiologic behavior remains incompletely understood. Common structural features have become apparent. Most transcription factors have DNA-binding domains sharing homologous structural motifs (cytosine-rich regions called zinc fingers, leucine-rich regions called leucine zippers, and so on), but other regions appear to be unique. Many factors implicated in the regulation of growth, differentiation, and development (e.g., homeobox genes, proto-oncogenes, antioncogenes) appear to be DNA-binding proteins and may be involved in the steps needed for activation of a gene within chromatin. Others bind to or modify DNA-binding proteins. These factors are discussed in more detail in several other chapters.

REGULATION OF mRNA SPLICING, STABILITY, AND TRANSLATION (POSTTRANSCRIPTIONAL REGULATION)

It has become increasingly apparent that posttranscriptional and translational mechanisms are important strategies used by cells to govern the amounts of mRNA and protein accumulating when a particular gene is expressed. The major modes of posttranscriptional regulation at the mRNA level are regulated alternative mRNA splicing, control of mRNA stability, and control of translational efficiency. As discussed elsewhere (see Chapter 3), additional regulation at the protein level occurs by mechanisms modulating localization, stability, activation, or export of the protein.

A cell can regulate the relative amounts of different protein isoforms arising from a given gene by altering the relative amounts of an mRNA precursor that are spliced along one pathway or another (alternative mRNA splicing). Many striking examples of this type of regulation are known—for example, the ability of B lymphocytes to make both IgM and IgD at the same developmental stage, changes in the particular isoforms of cytoskeletal proteins produced during red blood cell differentiation, and a switch from one isoform of the *c-myb* proto-oncogene product to another during red blood cell differentiation. Abnormalities in mRNA splicing due to mutations at the splice sites can lead to defective protein synthesis, as can occur in B-globin leading to a form of B-thalassemia. The effect of controlling the pathway of mRNA processing used in a cell is to include or exclude portions of the mRNA sequence. These portions encode peptide sequences that influence the ultimate physiologic behavior of the protein, or the RNA sequences that alter stability or translatability.

The importance of the control of mRNA stability for gene regulation is being increasingly appreciated. The steady-state level of any given mRNA species ultimately depends on the balance between the rate of its production (transcription and mRNA processing) and its destruction. One means by which stability is regulated is the inherent structure of the mRNA sequence, especially the 3′ and 5′ UTRs. As already noted, these sequences appear to affect mRNA secondary structure, recognition by nucleases, or both. Different mRNAs thus have inherently longer or shorter half-lives, almost regardless of the cell type in which they are expressed. Some mRNAs tend to be highly unstable. In response to appropriate physiologic needs, they can thus be produced quickly and removed from the cell quickly when a need for them no longer exists. Globin mRNA, on the other hand, is inherently quite stable, with a half-life measured in the range of 15 to 50 hours. This is appropriate for the need of reticulocytes to continue to synthesize globin for 24 to 48 hours after the ability to synthesize new mRNA has been lost by the terminally mature erythroblasts.

The stability of mRNA can also be altered in response to changes in the intracellular milieu. This phenomenon usually involves nucleases capable of destroying one or more broad classes of mRNA defined on the basis of their 3′ or 5′ UTR sequences. Thus, for example, histone mRNAs are destabilized after the S phase of the cell cycle is complete. Presumably this occurs because histone synthesis is no longer needed. Induction of cell activation, mitogenesis, or terminal differentiation events often results in the induction of nucleases that destabilize specific subsets of mRNAs. Selective stabilization of mRNAs probably also occurs, but specific examples are less well documented.

The amount of a given protein accumulating in a cell depends on the amount of the mRNA present, the rate at which it is translated into the protein, and the stability of the protein. Translational efficiency depends on a number of variables, including polyadenylation and presence of the 5′ cap. The amounts and state of activation of protein factors needed for translation are also crucial. The secondary structure of the mRNA, particularly in the 5′ UTR, greatly influences the intrinsic translatability of an mRNA molecule by constraining the access of translation factors and ribosomes to the translation initiation signal in the mRNA. Secondary structures along the coding sequence of the mRNA may also have some impact on the rate of elongation of the peptide.

Changes in capping, polyadenylation, and translation factor efficiency affect the overall rate of protein synthesis within each cell. These effects tend to be global rather than specific to a particular gene product. However, these effects influence the relative amounts of different proteins made. mRNAs whose structures inherently lend themselves to more efficient translation tend to compete better for rate-limiting components of the translational apparatus, but mRNAs that are inherently less translatable tend to be translated less efficiently

in the face of limited access to other translational components. For example, the translation factor eIF-4 tends to be produced in higher amounts when cells encounter transforming or mitogenic events. This causes an increase in overall rates of protein synthesis but also leads to a selective increase in the synthesis of some proteins that were underproduced before mitogenesis.

Translational regulation of individual mRNA species is critical for some events important to blood cell homeostasis. For example, as discussed in Chapter 33, the amount of iron entering a cell is an exquisite regulator of the rate of ferritin mRNA translation. An mRNA sequence called the *iron response element* is recognized by a specific mRNA-binding protein but only when the protein lacks iron. mRNA bound to the protein is translationally inactive. As iron accumulates in the cell, the protein becomes iron bound and loses its affinity for the mRNA, resulting in translation into apoferritin molecules that bind the iron.

Tubulin synthesis involves coordinated regulation of translation and mRNA stability. Tubulin regulates the stability of its own mRNA by a feedback loop. As tubulin concentrations rise in the cell, it interacts with its own mRNA through the intermediary of an mRNA-binding protein. This results in the formation of an mRNA–protein complex and nucleolytic cleavage of the mRNA. The mRNA is destroyed, and further tubulin production is halted.

These few examples of posttranscriptional regulation emphasize that cells tend to use every step in the complex pathway of gene expression as points at which exquisite control over the amounts of a particular protein can be regulated. In other chapters, additional levels of regulation are described (e.g., regulation of the stability, activity, localization, and access to other cellular components of the proteins that are present in a cell).

SMALL INTERFERING RNA AND MICRO RNA

Recently, posttranscriptional mechanisms of gene silencing involving small RNAs were discovered. One process is carried out by small interfering RNAs (siRNAs): short, double-stranded fragments of RNA containing 21 to 23 bp (Fig. 1-6). The process is triggered by perfectly complementary double-stranded RNA, which is cleaved by Dicer, a member of the RNase III family, into siRNA fragments. These small fragments of double-stranded RNA are unwound by a helicase in the RNA-induced silencing complex. The antisense strand anneals to mRNA transcripts in a sequence-specific manner and in doing so brings the endonuclease activity within the RNA-induced silencing complex to the targeted transcript. An RNA-dependent RNA polymerase in the RNA-induced silencing complex may then create new siRNAs to processively degrade the mRNA, ultimately leading to complete degradation of the mRNA transcript and abrogation of protein expression.

Although this endogenous process likely evolved to destroy invading viral RNA, the use of siRNA has become a commonly used tool for evaluation of gene function. Sequence-specific synthetic siRNA may be directly introduced into cells or introduced via gene transfertion methods and targeted to an mRNA of a gene of interest. The siRNA will lead to degradation of the mRNA transcript, and accordingly prevent new protein translation. This technique is a relatively simple, efficient, and inexpensive means to investigate cellular phenotypes after directed elimination of expression of a single gene. The 2006 Nobel Prize in Physiology or Medicine was awarded to two discoverers of RNA interference, Andrew Fire and Craig Mello.

Micro RNAs (miRNAs) are 22-nt small RNAs encoded by the cellular genome that alter mRNA stability and protein translation. These genes are transcribed by RNA polymerase II and capped and polyadenylated similar to other RNA polymerase II transcripts. The precursor transcript of approximately 70 nucleotides is cleaved into mature miRNA by the enzymes Drosha and Dicer. One strand of the resulting duplex forms a complex with the RNA-induced silencing complex that together binds the target mRNA with imperfect complementarity. Through mechanisms that are still incompletely understood, miRNA suppresses gene expression, likely either through inhibition of protein translation or through destabilization of mRNA. miRNAs appear to have essential roles in development and differentiation and may be aberrantly regulated in cancer cells. The identification of miRNA sequences, their regulation, and their target genes are areas of intense study.

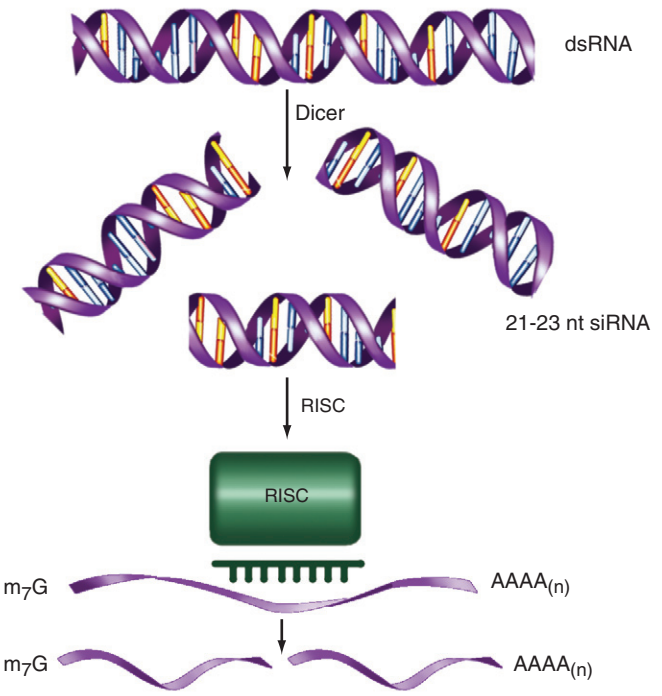

Figure 1-6 mRNA DEGRADATION BY siRNA. Double-stranded RNA is digested into 21- to 23-bp small interfering RNAs (siRNAs) by the Dicer RNase. These RNA fragments are unwound by RISC and bring the endonucleolytic activity of RNA-induced silencing complex (RISC) to messenger RNA (mRNA) transcripts in a sequence-specific manner, leading to degradation of the mRNA.

ADDITIONAL STRUCTURAL FEATURES OF GENOMIC DNA

Most DNA does not code for RNA or protein molecules. The vast majority of nucleotides present in the human genome reside outside structural genes. Structural genes are separated from one another by as few as 1 to 5 kilobases or as many as several thousand kilobases of DNA. Almost nothing is known about the reason for the erratic clustering and spacing of genes along chromosomes. It is clear that intergenic DNA contains a variegated landscape of structural features that provide useful tools to localize genes, identify individual human beings as unique from every other human being (DNA fingerprinting), and diagnose human diseases by linkage. Only a brief introduction is provided here.

The rate of mutation in DNA under normal circumstances is approximately $1/10^6$. In other words, one of 1 million bases of DNA will be mutated during each round of DNA replication. A set of enzymes called *DNA proofreading enzymes* corrects many but not all of these mutations. When these enzymes are themselves altered by mutation, the rate of mutation (and therefore the odds of neoplastic transformation) increases considerably. If these mutations occur in bases critical to the structure or function of a protein or gene, altered function, disease, or a lethal condition can result. Most pathologic mutations tend not to be preserved throughout many generations because of their unfavorable phenotypes. Exceptions, such as the hemoglobinopathies, occur when the heterozygous state for these

mutations confers selective advantage in the face of unusual environmental conditions, such as malaria epidemics. These "adaptive" mutations drive the dynamic change in the genome with time (evolution).

Most of the mutations that accumulate in the DNA of *Homo sapiens* occur in either intergenic DNA or the "silent" bases of DNA, such as the degenerate third bases of codons. They do not pathologically alter the function of the gene or its products. These clinically harmless mutations are called *DNA polymorphisms*. DNA polymorphisms can be regarded in exactly the same way as other types of polymorphisms that have been widely recognized for years (e.g., eye and hair color, blood groups). They are variations in the population that occur without apparent clinical impact. Each of us differs from other humans in the precise number and type of DNA polymorphisms that we possess.

Similar to other types of polymorphisms, DNA polymorphisms breed true. In other words, if an individual's DNA contains a G 1200 bases upstream from the α-globin gene, instead of the C most commonly found in the population, that G will be transmitted to that individual's offspring. Note that if one had a means for distinguishing the G at that position from a C, one would have a linked marker for that individual's α-globin gene.

Occasionally, a DNA polymorphism falls within a restriction endonuclease site. (Restriction enzymes cut DNA molecules into smaller pieces but only at limited sites, defined by short base sequences recognized by each enzyme.) The change could abolish the site or create a site where one did not exist before. These polymorphisms change the array of fragments generated when the genome is digested by that restriction endonuclease. This permits detection of the polymorphism by use of the appropriate restriction enzyme. This specific class of polymorphisms is thus called *restriction fragment length polymorphisms* (RFLPs).

Restriction fragment length polymorphisms are useful because the length of a restriction endonuclease fragment on which a gene of interest resides provides a linked marker for that gene. The exploitation of this fact for diagnosis of genetic diseases and detection of specific genes is discussed in Chapter 137; Fig. 1-7 shows a simple example.

Restriction fragment length polymorphisms have proved to be extraordinarily useful for the diagnosis of genetic diseases, especially when the precise mutation is not known. Recall that DNA polymorphisms breed true in the population. For example, as discussed in Chapter 137, a mutation that causes hemophilia will, when it occurs on the X chromosome, be transmitted to subsequent generations attached to the pattern (often called a framework or haplotype) of RFLPs that was present on that same X chromosome. If the pattern of RFLPs in the parents is known, the presence of the abnormal chromosome can be detected in the offspring.

An important feature of the DNA landscape is the high degree of repeated DNA sequence. A DNA sequence is said to be repeated if it or a sequence very similar (homologous) to it occurs more than once in a genome. Some multicopy genes, such as the histone genes and the ribosomal RNA genes, are repeated DNA sequences. Most repeated DNA occurs outside genes, or within introns. Indeed, 30% to 45% of the human genome appears to consist of repeated DNA sequences.

The function of repeated sequences remains unknown, but their presence has inspired useful strategies for detecting and characterizing individual genomes. For example, a pattern of short repeated DNA sequences, characterized by the presence of flanking sites recognized by the restriction endonuclease Alu-1 (called Alu-repeats), occurs approximately 300,000 times in a human genome. These sequences are not present in the mouse genome. If one wishes to infect mouse cells with human DNA and then identify the human DNA sequences in the infected mouse cells, one simply probes for the presence of Alu-repeats. The Alu-repeat thus serves as a signature of human DNA.

Classes of highly repeated DNA sequences (tandem repeats) have proved to be useful for distinguishing genomes of each human individual. These short DNA sequences, usually less than a few hundred bases long, tend to occur in clusters, with the number of repeats varying among individuals (see Fig. 1-6). Alleles of a given gene can therefore be associated with a variable number of tandem repeats (VNTR) in different individuals or populations. For example, there is a VNTR near the insulin gene. In some individuals or populations, it is present in only a few tandem copies, but in others, it is present in many more. When the population as a whole is examined, there is a wide degree of variability from individual to individual as to the number of these repeats residing near the insulin gene. It can readily be imagined that if probes were available to detect a dozen or so distinct VNTR regions, each human individual would differ from virtually all others with respect to the aggregate pattern of these VNTRs. Indeed, it can be shown mathematically that the probability of any two human beings' sharing exactly the same pattern of VNTRs is exceedingly small if approximately 10 to 12 different VNTR elements are mapped for each person. A technique called *DNA fingerprinting* that is based on VNTR analysis has become widely publicized because of its forensic applications.

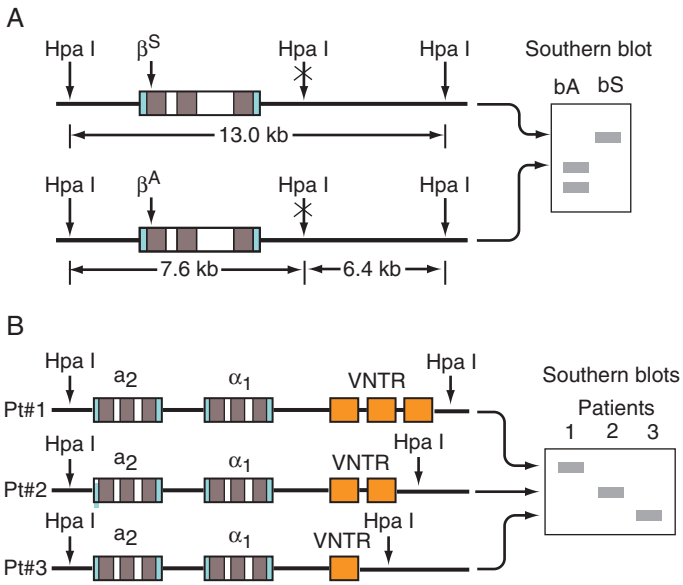

Figure 1-7 TWO USEFUL FORMS OF SEQUENCE VARIATION AMONG THE GENOMES OF NORMAL INDIVIDUALS. **A,** Presence of a DNA sequence polymorphism that falls within a restriction endonuclease site, thus altering the pattern of restriction endonuclease digests obtained from this region of DNA on Southern blot analysis. (Readers not familiar with Southern blot analysis should return to examine this figure after reading later sections of this chapter.) **B,** A variable-number tandem repeat (VNTR) region (defined and discussed in the text). Note that individuals can vary from one to another in many ways according to how many repeated units of the VNTR are located on their genomes, but restriction fragment length polymorphism differences are in effect all-or-none differences, allowing for only two variables (restriction site presence or absence).

Variable-number tandem repeats can be regarded as normal sequence variations in DNA that are similar to, but far more useful than, single-base-change RFLPs. Note that the odds of a single base change altering a convenient restriction endonuclease site are relatively small, so that RFLPs occur relatively infrequently in a useful region of the genome. Moreover, there is only one state or variable that can be examined—that is, the presence or absence of the restriction site. By contrast, many VNTRs are scattered throughout the human genome. Most of these can be distinguished from one another quite readily by standard methods. Most important, the amount of variability from individual to individual at each site of a VNTR is considerably greater than for RFLPs. Rather than the mere presence or absence of a site, a whole array of banding patterns is possible, depending on how many individual repeats are present at that site (see Fig. 1-6). This reasoning can readily be extended to

appreciate that VNTRs occurring near genes of hematologic interest can provide highly useful markers for localizing that gene or for distinguishing the normal allele from an allele carrying a pathologic mutation.

More recently, genomic technologies have made it possible to characterize single nucleotide polymorphisms in large stretches of DNA whether or not they alter restriction endonuclease sites. Single nucleotide polymorphism analysis is gaining momentum as a means for characterizing genomes.

There are many other classes of repeated sequences in human DNA. For example, human DNA has been invaded many times in its history by retroviruses. Retroviruses tend to integrate into human DNA and then "jump out" of the genome when they are reactivated, to complete their life cycle. The proviral genomes often carry with them nearby bits of the genomic DNA in which they sat. If the retrovirus infects the DNA of another individual at another site, it will insert this genomic bit. Through many cycles of infection, the virus will act as a transposon, scattering its attached sequence throughout the genome. These types of sequences are called *long interspersed elements*. They represent footprints of ancient viral infections.

KEY METHODS FOR GENE ANALYSIS

The foundation for the molecular understanding of gene structure and expression is based on fundamental molecular biologic techniques that were developed in the 1970s and 1980s. These techniques allow for the reduction of the multibillion nucleotide genome into smaller fragments that are more easily analyzed. Several key methods are outlined here.

Restriction Endonucleases

Naturally occurring bacterial enzymes called *restriction endonucleases* catalyze sequence-specific hydrolysis of phosphodiester bonds in the DNA backbone. For example, EcoRI, a restriction endonuclease isolated from *Escherichia coli,* cleaves DNA only at the sequence 5′-GAATTC-3′. Thus, each DNA sample will be reproducibly reduced to an array of fragments whose size ranges depend on the distribution with which that sequence exists within the DNA. A specific six-nucleotide sequence would be statistically expected to appear once every 46 (or 4096) nucleotides, but in reality, the distance between specific sequences varies greatly. Using combinations of restriction endonucleases, DNA several hundred million base pairs in length can be reproducibly reduced to fragments ranging from a few dozen to tens of thousands of base pairs long. These smaller products of enzymatic digestion are much more manageable experimentally. Genetic "fingerprinting," or restriction enzyme maps of genomes, can be constructed by analyzing the DNA fragments resulting from digestion. Many enzymes cleave DNA so as to leave short, single-stranded overhanging regions that can be enzymatically linked to other similar fragments, generating artificially recombined, or recombinant, DNA molecules. These ligated gene fragments can then be inserted into bacteria to produce more copies of the recombinant molecules or to express the cloned genes.

DNA, RNA, and Protein Blotting

There are many ways that a cloned DNA sequence can be exploited to characterize the behavior of normal or pathologic genes. Blotting methods deserve special mention because of their widespread use in clinical and experimental hematology. A cloned DNA fragment can be easily purified and tagged with a radioactive or nonradioactive label. The fragment provides a pure and highly specific molecular hybridization probe for the detection of complementary DNA or RNA molecules in any specimen of DNA or RNA. One set of assays that has proved particularly useful involves Southern blotting, named after Dr E. Southern, who invented the method (Fig. 1-8). Southern blotting allows detection of a specific gene, or region in or near a gene, in a DNA preparation. The DNA is isolated and digested with one or more restriction endonucleases, and the resulting fragments are denatured and separated according to their molecular size by electrophoresis through agarose gels. By means of capillary action in a high salt buffer, the DNA fragments are passively transferred to a nitrocellulose or nylon membrane. Single-stranded DNA and RNA molecules attach noncovalently but tightly to the membrane. In this fashion, the membrane becomes a replica, or blot, of the gel. After the blotting procedure is complete, the membrane is incubated in a hybridization buffer containing the radioactively labeled probe. The probe hybridizes only to the gene of interest and renders radioactive only one or a few bands containing complementary sequences. After appropriate washing and drying, the bands can be visualized by autoradiography.

Digestion of a DNA preparation with several different restriction enzymes allows a restriction endonuclease map of a gene in the

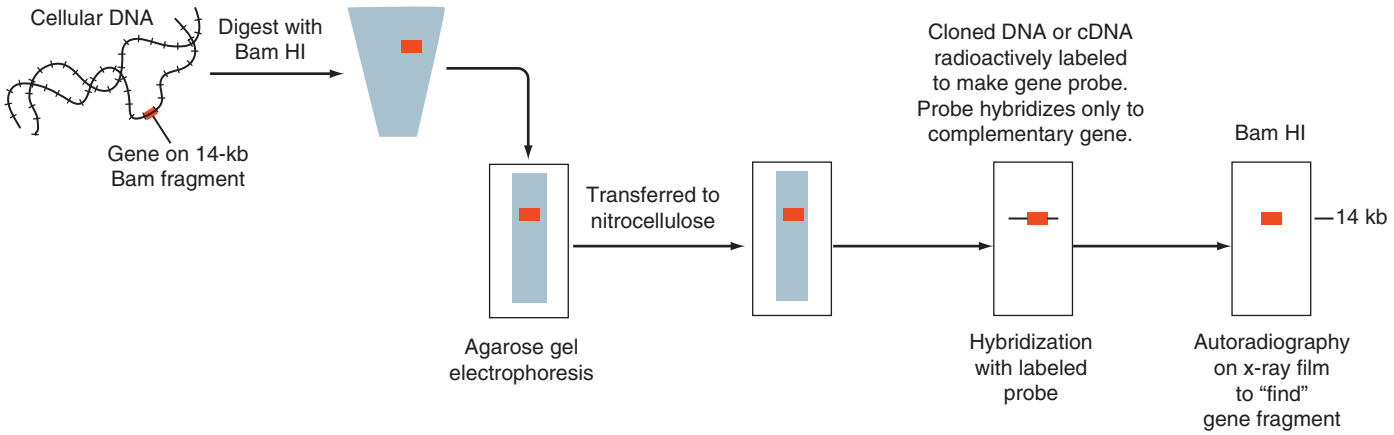

Figure 1-8 SOUTHERN GENE BLOTTING. Detection of a genomic gene *(red)* that resides on a 14-kb Bam HI fragment. To identify the presence of a gene in the genome and the size of the restriction fragment on which it resides, genomic DNA is digested with a restriction enzyme, and the fragments are separated by agarose gel electrophoresis. Human genomes contain from several hundred thousand to 1 million sites for any particular restriction enzyme, which results in a vast array of fragments and creates a blur or streak on the gel; one fragment cannot be distinguished from another readily. If the DNA in the gel is transferred to nitrocellulose by capillary blotting, however, it can be further analyzed by molecular hybridization to a radioactive cDNA probe for the gene. Only the band containing the gene yields a positive autoradiography signal, as shown. If a disease state were to result in loss of the gene, alteration of its structure, or mutation (altering recognition sites for one or more restriction enzymes), the banding pattern would be changed.

human genome to be constructed. Southern blotting has thus become a standard way of characterizing the configuration of genes in the genome.

Northern blotting represents an analogous blotting procedure used to detect RNA. RNA cannot be digested with restriction enzymes (which cut only DNA); rather, the intact RNA molecules can be separated according to molecular size by electrophoresis through the gel (mRNAs are 0.5-12 kilobases in length), transferred onto membranes, and probed with a DNA probe. In this fashion, the presence, absence, molecular size, and number of individual species of a particular mRNA species can be detected.

Western blotting is a similar method that can be used to examine protein expression. Cellular lysates (or another source of proteins) can be electrophoresed through a polyacrylamide gel so as to separate proteins on the basis of their apparent molecular sizes. The resolved proteins can then be electrically transferred to nitrocellulose membranes and probed with specific antibodies directed against the protein of interest. As with RNA analysis, the relative expression levels and molecular sizes of proteins can be assessed with this method.

Polymerase Chain Reaction

The development of the polymerase chain reaction (PCR) was a major breakthrough that has revolutionized the utility of a DNA-based strategy for diagnosis and treatment. It permits the detection, synthesis, and isolation of specific genes and allows differentiation of alleles of a gene differing by as little as one base. It does not require sophisticated equipment or unusual technical skills. A clinical specimen consisting of only minute amounts of tissue will suffice; in most circumstances, no special preparation of the tissue is necessary. PCR thus makes recombinant DNA techniques accessible to clinical laboratories. This single advance has produced a quantum increase in the use of direct gene analysis for diagnosis of human diseases.

The PCR is based on the prerequisites for copying an existing DNA strand by DNA polymerase: an existing denatured strand of DNA to be used as the template and a primer. Primers are short oligonucleotides, 12 to 100 bases in length, having a base sequence complementary to the desired region of the existing DNA strand. The enzyme requires the primer to "know" where to begin copying. If the base sequence of the DNA of the gene under study is known, two synthetic oligonucleotides complementary to sequences flanking the region of interest can be prepared. If these are the only oligonucleotides present in the reaction mixture, then the DNA polymerase can only copy daughter strands of DNA downstream from those oligonucleotides. Recall that DNA is double stranded, that the strands are held together by the rules of Watson-Crick base pairing, and that they are aligned in antiparallel fashion. This implies that the effect of incorporation of both oligonucleotides into the reaction mix will be to synthesize two daughter strands of DNA, one originating upstream of the gene and the other originating downstream. The net effect is synthesis of only the DNA between the two primers, thus doubling only the DNA containing the region of interest. If the DNA is now heat denatured, allowing hybridization of the daughter strands to the primers, and the polymerization is repeated, then the region of DNA through the gene of interest is doubled again. Thus, two cycles of denaturation, annealing, and elongation result in a selective quadrupling of the gene of interest. The cycle can be repeated 30 to 50 times, resulting in a selective and geometric amplification of the sequence of interest to the order of 2^{30} to 2^{50} times. The result is a millionfold or higher selective amplification of the gene of interest, yielding microgram quantities of that DNA sequence.

The PCR achieved practical utility when DNA polymerases from thermophilic bacteria were discovered; when synthetic oligonucleotides of any desired sequence could be produced efficiently, reproducibly, and cheaply by automated instrumentation; and when DNA thermocycling machines were developed. Thermophilic bacteria live in hot springs and other exceedingly warm environments, and their DNA polymerases can tolerate 100° C (212° F) incubations without substantial loss of activity. The advantage of these thermostable polymerases is that they retain activity in a reaction mix that is repeatedly heated to the high temperature needed to denature the DNA strands into the single-stranded form. Microprocessor-driven DNA thermocycler machines can be programmed to increase temperatures to 95° C to 100° C (203° F to 212° F) (denaturation), to cool the mix to 50° C (101° F) rapidly (a temperature that favors oligonucleotide annealing), and then to raise the temperature to 70° C to 75° C (141.4° F to 151.5° F) (the temperature for optimal activity of the thermophilic DNA polymerases). In a reaction containing the test specimen, the thermophilic polymerase, the primers, and the chemical components (e.g., nucleotide subunits), the thermocycler can conduct many cycles of denaturation, annealing, and polymerization in a completely automated fashion. The gene of interest can thus be amplified more than a millionfold in a matter of a few hours. The DNA product is readily identified and isolated by routine agarose gel electrophoresis. The DNA can then be analyzed by restriction endonuclease, digestion, hybridization to specific probes, sequencing, further amplification by cloning, and so forth.

USE OF TRANSGENIC AND KNOCKOUT MICE TO DEFINE GENE FUNCTION

Recombinant DNA technology has resulted in the identification of many disease-related genes. To advance the understanding of the disease related to a previously unknown gene, the function of the protein encoded by that gene must be verified or identified, and the way changes in the gene's expression influence the disease phenotype must be characterized. Analysis of the role of these genes and their encoded proteins has been made possible by the development of recombinant DNA technology that allows the production of mice that are genetically altered at the cloned locus. Mice can be produced that express an exogenous gene and thereby provide an in vivo model of its function. Linearized DNA is injected into a fertilized mouse oocyte pronucleus and reimplanted in a pseudopregnant mouse. The resultant transgenic mice can then be analyzed for the phenotype induced by the injected transgene. Placing the gene under the control of a strong promoter that stimulates expression of the exogenous gene in all tissues allows the assessment of the effect of widespread overexpression of the gene. Alternatively, placing the gene under the control of a promoter that can function only in certain tissues (a tissue-specific promoter) elucidates the function of that gene in a particular tissue or cell type. A third approach is to study control elements of the gene by testing their capacity to drive expression of a "marker" gene that can be detected by chemical, immunologic, or functional means. For example, the promoter region of a gene of interest can be joined to the cDNA encoding green jellyfish protein and activity of the gene assessed in various tissues of the resultant transgenic mouse by fluorescence microscopy. Use of such a reporter gene demonstrates the normal distribution and timing of expression of the gene from which the promoter elements are derived. Transgenic mice contain exogenous genes that insert randomly into the genome of the recipient. Expression can thus depend as much on the location of the insertion as it does on the properties of the injected DNA.

In contrast, any defined genetic locus can be specifically altered by targeted recombination between the locus and a plasmid carrying an altered version of that gene (Fig. 1-9). If a plasmid contains that altered gene with enough flanking DNA identical to that of the normal gene locus, homologous recombination can occur, and the altered gene in the plasmid will replace the gene in the recipient cell. Using a mutation that inactivates the gene allows the production of a null mutation, in which the function of that gene is completely lost. To induce such a mutation, the plasmid is introduced into an embryonic stem cell, and the rare cells that undergo homologous recombination are selected. The "knockout" embryonic stem cell is then introduced into the blastocyst of a developing embryo. The resultant animals are chimeric; only a fraction of the cells in the animal contain the targeted gene. If the new gene is introduced into some of the germline cells of the chimeric mouse, then some of the offspring of that mouse will carry the mutation as a gene in all of

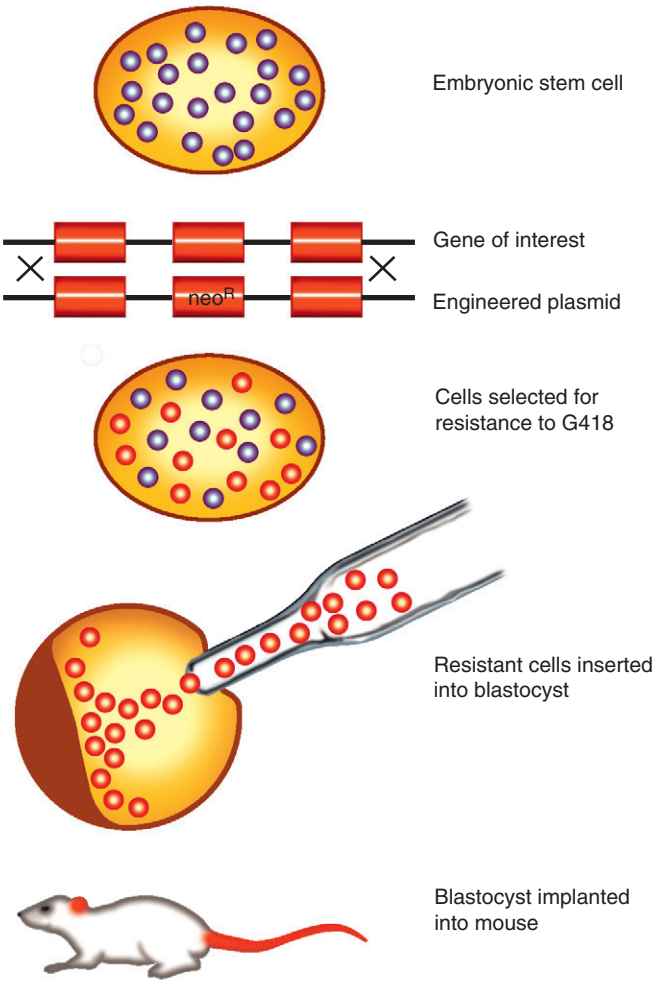

Figure 1-9 GENE "KNOCKOUT" BY HOMOLOGOUS RECOMBINATION. A plasmid containing genomic DNA homologous to the gene of interest is engineered to contain a selectable marker positioned so as to disrupt expression of the native gene. The DNA is introduced into embryonic stem cells, and cells resistant to the selectable marker are isolated and injected into a mouse blastocyst, which is then implanted into a mouse. Offspring mice that contain the knockout construct in their germ cells are then propagated, yielding mice with heterozygous or homozygous inactivation of the gene of interest.

their cells. These heterozygous mice can be further bred to produce mice homozygous for the null allele. Such knockout mice reveal the function of the targeted gene by the phenotype induced by its absence. Genetically altered mice have been essential for discerning the biologic and pathologic roles of large numbers of genes implicated in the pathogenesis of human disease.

DNA-BASED THERAPIES

Gene Therapy

The application of gene therapy to genetic hematologic disorders is an appealing idea. In most cases, this would involve isolating hematopoietic stem cells from patients with diseases with defined genetic lesions, inserting normal genes into those cells, and reintroducing the genetically engineered stem cells back into the patient. A few candidate diseases for such therapy include sickle cell disease, thalassemia, hemophilia, and adenosine deaminase–deficient severe combined immunodeficiency. The technology for separating hematopoietic stem cells and for performing gene transfer into those cells has advanced rapidly, and clinical trials have begun to test the applicability of these techniques. However, despite the fact that gene therapy has progressed to the enrollment of patients in clinical protocols, major technical problems still need to be solved, and there are no proven therapeutic successes from gene therapy. However, progress in this field continues rapidly. The scientific basis for gene therapy and the clinical issues surrounding this approach are discussed in Chapter 99.

Antisense Therapy

The recognition that abnormal expression of oncogenes plays a role in malignancy has stimulated attempts to suppress oncogene expression to reverse the neoplastic phenotype. One way of blocking mRNA expression is with antisense oligonucleotides. These are single-stranded DNA sequences, 17 to 20 bases long, having a sequence complementary to the transcription or translation start of the mRNA. These relatively small molecules freely enter the cell and complex to the mRNA by their complementary DNA sequence. This often results in a decrease in gene expression. The binding of the oligonucleotide may directly block translation and clearly enhances the rate of mRNA degradation. This technique has been shown to be promising in suppressing expression of bcr-abl and to suppress cell growth in chronic myelogenous leukemia. The technique is being tried as a therapeutic modality for the purging of tumor cells before autologous transplantation in patients with chronic myelogenous leukemia.

FUTURE DIRECTIONS

The elegance of recombinant DNA technology resides in the capacity it confers on investigators to examine each gene as a discrete physical entity that can be purified, reduced to its basic building blocks for decoding of its primary structure, analyzed for its patterns of expression, and perturbed by alterations in sequence or molecular environment so that the effects of changes in each region of the gene can be assessed. Purified genes can be deliberately modified or mutated to create novel genes not available in nature. These provide the potential to generate useful new biologic entities, such as modified live virus or purified peptide vaccines, modified proteins customized for specific therapeutic purposes, and altered combinations of regulatory and structural genes that allow for the assumption of new functions by specific gene systems.

Purified genes facilitate the study of gene regulation in many ways. First, a cloned gene provides characterized DNA probes for molecular hybridization assays. Second, cloned genes provide the homogeneous DNA moieties needed to determine the exact nucleotide sequence. Sequencing techniques have become so reliable and efficient that it is often easier to clone the gene encoding a protein of interest and determine its DNA sequence than it is to purify the protein and determine its amino acid sequence. The DNA sequence predicts exactly the amino acid sequence of its protein product. By comparing normal sequences with the sequences of alleles cloned from patients known to be abnormal, such as the globin genes in the thalassemia or sickle cell syndromes, the normal and pathologic anatomy of genes critical to major hematologic diseases can be established. In this manner, it has been possible to identify many mutations responsible for various forms of thalassemia, hemophilia, thrombasthenia, red blood cell enzymopathies, porphyrias, and so forth. Similarly, single base changes have been shown to be the difference between many normally functioning proto-oncogenes and their cancer-promoting oncogene derivatives.

Third, cloned genes can be manipulated for studies of gene expression. Many vectors allowing efficient transfer of genes into eukaryotic cells have been perfected. Gene transfer technologies allow the gene to be placed into the desired cellular environment and the expression of that gene or the behavior of its products to be analyzed. These

surrogate or reverse genetics systems allow analysis of the normal physiology of expression of a particular gene, as well as the pathophysiology of abnormal gene expression resulting from mutations.

Fourth, cloned genes enhance study of their protein products. By expressing fragments of the gene in microorganisms or eukaryotic cells, customized regions of a protein can be produced for use as an immunogen, thereby allowing preparation of a variety of useful and powerful antibody probes. Alternatively, synthetic peptides deduced from the DNA sequence can be prepared as the immunogen. Controlled production of large amounts of the protein also allows direct analysis of specific functions attributable to regions in that protein.

Finally, all of the aforementioned techniques can be extended by mutating the gene and examining the effects of those mutations on the expression of or the properties of the encoded mRNAs and proteins. By combining portions of one gene with another (chimeric genes) or abutting structural regions of one gene with regulatory sequences of another, the researcher can investigate in previously inconceivable ways the complexities of gene regulation. These activist approaches to modifying gene structure or expression create the opportunity to generate new RNA and protein products whose applications are limited only by the collective imagination of the investigators.

The most important impact of the genetic approach to the analysis of biologic phenomena is the most indirect. Diligent and repeated application of the methods outlined in this chapter to the study of many genes from diverse groups of organisms is beginning to reveal the basic strategies used by nature for the regulation of cell and tissue behavior. As our knowledge of these rules of regulation grows, our ability to understand, detect, and correct pathologic phenomena will increase substantially.

CHAPTER 2

GENOMIC APPROACHES TO HEMATOLOGY

Todd R. Golub

The publication of the initial draft sequence of the human genome in 2001 heralded a new era of biomedical research. Just as molecular biology changed the face of research in the 1970s and 1980s, genomics promises a novel perspective into the biologic basis of human disease. Genomics involves the systematic study of biologic systems, typically focusing on aspects of the genome (e.g., DNA and its derivatives RNA and protein). However, a major tenet of genomics research involves *hypothesis-generating* data collection as opposed to *hypothesis-testing* experimentation. The latter has formed the basis of biomedical research, whereby existing knowledge and insight guide the testing of a particular hypothesis. In contrast, genome-based research tends to make few prior assumptions, favoring unbiased data generation and analysis as a path to discovery. Clearly, both approaches are powerful and essential, and both should continue full force in the future.

As attractive as unbiased, comprehensive genomic analysis may be, there have until recently been severe limitations to the approach. Most importantly, systematic approaches (e.g., to genome sequencing) have been cost prohibitive. However, sequencing costs have fallen dramatically over the past decade (by more than 10,000-fold), making it now possible to routinely characterize the genome at the level of DNA and RNA variation. Although less dramatic technical advances have been made in the area of protein analysis, proteomics is also undergoing technologic change that makes future prospects of systematic interrogation of entire proteomes conceivable in the near future.

With the ability to generate data of unprecedented scale comes the challenge of data analysis. This has driven an entirely new generation of computer scientists to focus on new approaches to genomic data analysis, leading to new methods of pattern recognition in voluminous, often noisy data. The challenge going forward will be that of translating these data into useful knowledge that provides biologic insight and clinical utility.

This chapter describes the principles underlying common genomic approaches in the study of hematologic and other diseases, focusing more on concepts than on technical detail. Although genomic approaches are just beginning to be introduced into clinical practice, it is likely that there will be an enormous acceleration of the pace of utilization of genomic approaches in clinical research and clinical care in the years ahead.

PRINCIPLES OF GENOMIC APPROACHES

Hypothesis-Generating Versus Hypothesis-Testing

Genomic approaches to hematology, similar to genomic approaches to other aspects of biomedical research, differ fundamentally from traditional, hypothesis-based investigation. The backbone of the entire biomedical research enterprise is the formulation of specific hypotheses based on an accumulation of knowledge in the field coupled to rigorous experimental strategies to test those hypotheses in physiologically relevant systems. This approach has been highly successful and should continue as a pillar of modern hematology research. However, such hypothesis-based approaches may not be sufficient for a complete elucidation of the molecular basis of hematologic disease. To complement hypothesis-driven research, genomics-based, hypothesis-generating approaches have proven powerful.

Genomics approaches can in the narrowest sense be seen as studies of DNA. However, a more liberal definition may be useful—namely, a systematic, unbiased approach that is not necessarily dependent on preexisting hypotheses. In this manner, one uses advanced technologies (focused on DNA, RNA, protein, or other measurements) to simply observe rather than to attempt to validate or invalidate a particular prior hypothesis. This approach can be particularly powerful when studying the biology of diseases without a known basis.

For example, the biology of polycythemia vera had been obscure despite decades of research until an unbiased search for mutations in the disease uncovered recurrent mutations in the gene encoding the tyrosine kinase Janus-activated kinase 2 (JAK2).[1,2] Nearly overnight, this finding established new directions for basic biologic research into the disease as well as mechanism-based drug development. Similarly, the molecular basis of certain myelodysplastic syndromes (MDS) has been entirely unknown, but recent unbiased genome sequencing approaches yielded common mutations in *SF3B1,* the gene encoding an RNA splicing factor in the majority of patients with refractory anemia with ringed sideroblasts.[3] Before this discovery, there was no reason to suspect defects in splicing machinery as the basis MDS.

Thus, although genomic approaches have been characterized by some as "fishing expeditions," it is clear that such strategies have the potential to dramatically accelerate understanding of disease, particularly in areas where the biologic basis is largely unknown.

Systematic and Comprehensive Measurements and Perturbations

A common feature of many genomic approaches is the systematic nature of the study (e.g., interrogating *all* kinases for their potential role in a particular biologic system). A more traditional approach would be to first determine (based on prior knowledge) the kinase (or kinases) most likely to be important and then develop highly validated assays for that particular kinase. A strength of the traditional approach is that the quality of the final assay is often high given the attention paid to the one (or a couple of) kinase(s) of interest. On the other hand, such an approach is limited by the quality of the initial hypothesis. In contrast, a genomic approach would be more systematic and comprehensive, attempting to screen all kinases for the phenotype of interest. Although this is compelling, it also comes with an important limitation—the quality of the assay for each kinase's activity may not be uniformly high. For example, a screen for kinase phosphorylation as surrogate for kinase activity has been reported.[4] Such an approach is limited by the sensitivity and specificity of kinase-directed antibodies, which can be enormously variable across kinase family members.

Although genomics is most commonly associated with systematic *observational* studies, the same principles can also be applied to *perturbational* studies (i.e., systematic modulation of proteins followed

by a phenotypic read-out). A particularly powerful approach has been the systematic knock-down of mRNA transcripts using RNA interference (RNAi). In this manner, all genes within a particular class (e.g., kinases) can be knocked down and the phenotypic consequence of each assessed. Most recently, genome-wide RNAi studies have been reported using lentivirus-delivered short hairpin RNAs (shRNAs) (see the Functional Genomics section later). Although large-scale perturbational profiling studies are performed primarily in specialized research centers today, it is highly likely that such approaches will become increasingly common in the years ahead.

IMPORTANCE OF SAMPLE ACQUISITION

Acquisition of the appropriate samples for a genomic experiment is arguably the most crucial step for the production of a dataset that will be rich with biologic information. This is particularly true for gene expression analysis in which a number of processes may affect the data. Because gene expression is a dynamic process that can be affected by any type of cellular manipulation, RNA abundance measurements are potentially complicated by changes that occur between the time that the biopsy is taken and the time that the RNA is isolated from the specimen. In general, the highest quality RNA is obtained if, as soon as possible after harvesting a sample, cells are dissolved in a solution such as Trizol that inactivates RNAse enzymes, and the sample is stored at −80° Celsius until RNA can be extracted. A number of amplification procedures have been developed, including those that use two rounds of in vitro transcription and those that take advantage of the polymerase chain reaction (PCR); these manipulations make for the ability to analyze increasingly tiny samples (containing as few as 1000 cells or less). In addition, recent technical advances have made it possible to measure mRNA expression from formalin-fixed paraffin-embedded (FFPE) samples in which the mRNA is typically degraded to approximately 80 nucleotides in length.[5] These newer methods may make it feasible to analyze large archives of FFPE tissues with long-term clinical follow-up (which is often lacking from more recently collected, frozen samples) and may represent a suitable platform for routine clinical implementation when the collection of frozen specimens is often impractical.

Another extremely important but complicated issue is the complexity of the mixture of cells present in the sample. If one's goal is to assess genomic changes that represent somatic rather than germline differences, then the sample needs to be enriched (often to >75%) in the cell of interest. This may not be an issue for bone marrow samples from patients with newly diagnosed leukemia in whom the number of blasts often approaches 90% or greater. But it may become an issue if one's desire is to analyze leukemia at the time of relapse. In this scenario, the relapse is often detected long before the bone marrow is completely replaced with leukemia, and thus the blasts may represent less than 50% of the mononuclear cells. Multiple methods are available for enrichment and selection of cells of interest from a biopsy sample; these methods include flow cytometry, immunomagnetic bead sorting, and laser-capture microdissection.[6] All have the benefit of enrichment of the cell of interest but also increase the amount of processing time and sample manipulation. Alternatively, "contaminating," nonmalignant cells may be included in gene expression signatures because these cells may reflect the tumor environment and may therefore carry important information.[7] This is most obvious for solid tumors in which the tumor stroma and infiltrating inflammatory cells likely influence the neoplastic cells, but all diseased cells exist in a complex environment and are thus no doubt influenced by their interactions. Thus dismissing these cells as contamination must be done with caution.

As discussed in subsequent sections on next-generation sequencing technologies, the admixture of nonmalignant cells within a tumor may not obscure the presence of mutations in the tumor cells even if those cells represent a minority population. However, the detection of mutations in a subset of cells within a sample requires extra depth of sequencing beyond what would be required to sequence, for example, a normal diploid genome. Thus it becomes critical to have a rough estimate of the purity of a given sample so that the appropriate genomic approach can be taken subsequently.

ANALYTICAL CONSIDERATIONS

Unsupervised Learning Approaches

Unsupervised learning approaches (often referred to as *clustering*) have become an important part of the discovery process in genomic analysis. This type of analysis involves grouping samples based solely on the data obtained without regard to any prior knowledge of the samples or the disease. Thus, one can obtain the predominant "structure" of the dataset without imposing any prior bias. For example, unsupervised learning approaches have been used to cluster leukemia or lymphoma samples based on their gene expression profiles with the goal of uncovering the most robust classification schemes.[8-11] Clustering algorithms can also cluster genes that have a similar expression profile in a gene expression data set. There are a number of methods for clustering genes and samples, all of which have computational strengths and weaknesses. Comparing the clustering methods is beyond the scope of this chapter, but suffice it to say that all identify major associations within a given data set if the signature is strong and robust. Great care must be taken in the interpretation of clustering results because clusters with distinct gene expression profiles may be caused not only by biologically important distinctions but also by artifacts of sample processing. Unsupervised learning methods that have been used include hierarchical clustering, principle component analysis, non-negative matrix factorization, and *k*-means clustering.

Supervised Learning Approaches

Supervised learning approaches are best suited for comparing data among two or more classes of samples that can be distinguished by some known property (or class distinction) such as biologic subtype or clinical outcome. For example, to determine the gene expression differences between different leukemia subtypes with distinct genetic abnormalities, one would use a supervised approach (Fig. 2-1). The same genes might be clustered together based on the unsupervised approaches already described, but they might also be obscured by a more dominant gene expression signature that had nothing to do with the distinction of interest. For example, if there was another major signature within the data (i.e., a stage of differentiation signature), the differences that the investigator was searching for might be lost. A number of metrics can be used to identify genes that are differentially expressed between two groups of samples, all of which are best suited to identify genes that are uniformly highly expressed in one group. Although the different metrics may generate slightly different lists of gene expression differences, if the gene expression difference is robust, all should give comparable results.

Challenges of High-Dimensional Data

With the ability to generate large-scale genomic datasets comes a number of analytical issues that are unique to what is known as "big data." In particular, when the number of features analyzed in an experiment (e.g., the expression of each of 22,000 mRNA transcripts) exceeds the number of samples (e.g., 50 patients with a particular type of lymphoma), there is potential for finding patterns in the data simply by chance. The more features analyzed and the fewer the number of samples, the more likely such a phenomenon is to be encountered. For this reason, the use of nominal *P* values to estimate statistical significance of an observed observation is generally discouraged. Rather, some approach to correcting for multiple hypothesis testing is in order (in the present example, 22,000 hypotheses are effectively being tested). In the absence of such

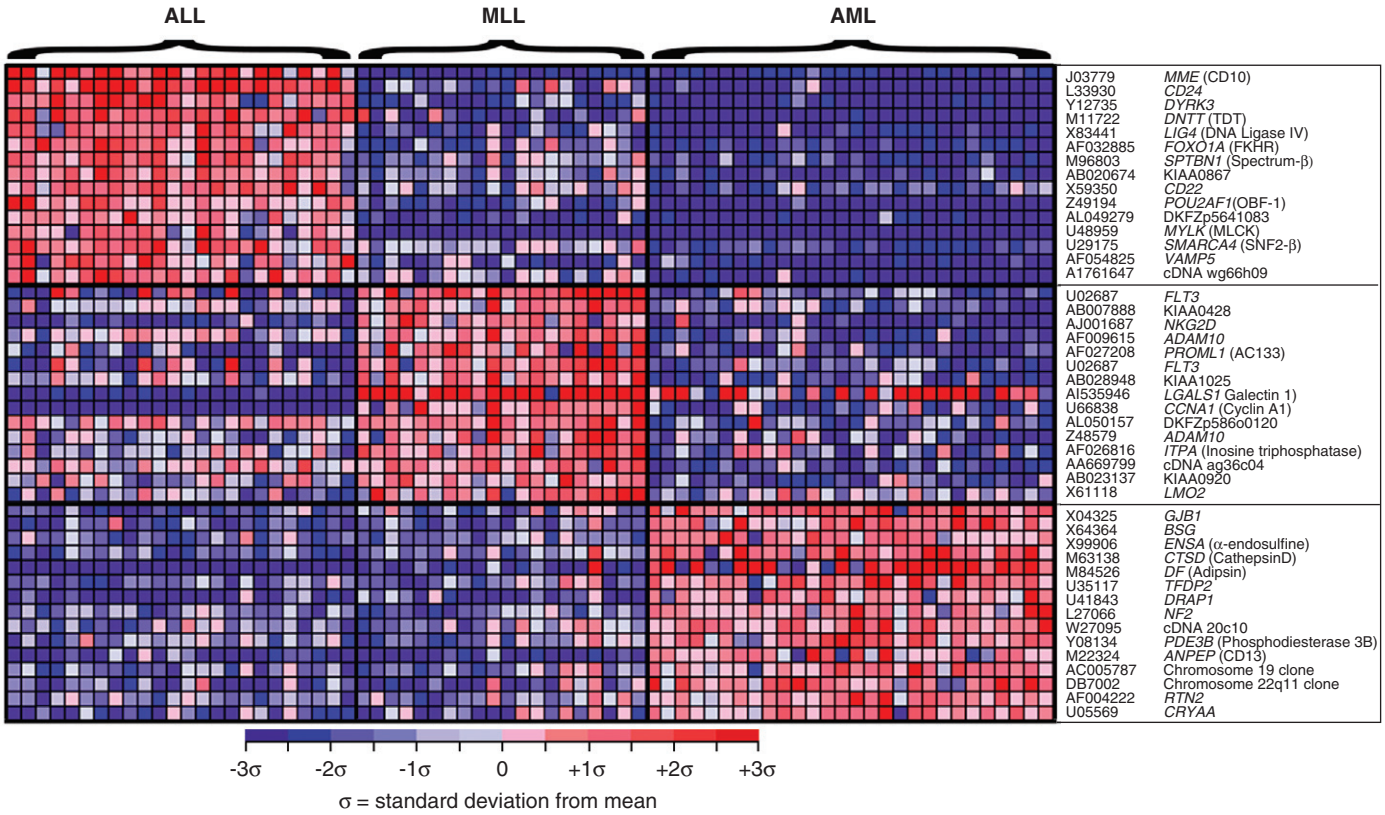

Figure 2-1 Comparison of gene expression in acute lymphocytic leukemia (ALL), *MLL*-rearranged ALL (designated MLL), and acute myelogenous leukemia (AML) samples using a supervised learning approach. Gene expression in leukemia samples was analyzed using Affymetrix microarrays containing 12,600 unique probe sets. Genes that are highly expressed in one type of leukemia relative to the other two are shown. Each column represents a patient sample, and each row represents a gene. *Red* represents relative high-level expression and relative low-level expression. *(From Armstrong SA, Staunton JE, Silverman LB, et al: MLL translocations specify a distinct gene expression profile that distinguishes a unique leukemia.* Nat Genet *30:41, 2002.)*

penalization, the significance of observations is likely to be grossly overestimated. Indeed, such misinterpretations of data were at the root of many of the early uses of gene expression profiling data in biomedical research.

Robustness of Pattern Recognition Algorithms

Related to the challenges with high-dimensional data described, special considerations of pattern-matching algorithms must be made. With the availability of high-dimensional gene expression profiling data in the late 1990s came a flood of computational innovation from computer scientists looking to find biologically meaningful patterns amid biologic data. With that early wave of computational analysis came the realization that with often limited numbers of samples (compared with the number of features analyzed) comes the possibility of "overfitting" a computational model to a particular dataset—that is, defining a pattern (e.g., a spectrum of genes that are differentially expressed) that is correlated with a phenotype of interest (e.g., survival) in an initial dataset but then does not predict accurately when applied to an independent dataset. This failure to reproduce initial findings was variously attributed to technical defects in the genomic data itself, insufficiently complex algorithms, and the possibility that perhaps the most important features were not being analyzed in the first place (e.g., noncoding RNAs). But, in fact, nearly all of the early failures of pattern recognition algorithms to validate when applied to new datasets were attributable to overfitting of the models to an initial, small dataset. The solution to this problem is to ensure that discovery datasets are sufficiently large to avoid overfitting and to insist that before any clinical or biologic claims are made the model is tested on completely independent samples.

NEXT-GENERATION SEQUENCING TECHNOLOGY

Distinguishing Features Compared With Sanger Sequencing

Beginning around 2006, a number of new approaches to DNA sequencing burst onto the scene. These technical advances have transformed the field of genomics and will likely equally transform the diagnostics field in the years to come. A number of novel sequencing approaches have been commercialized, and their details are beyond the scope of this chapter. However, they differ fundamentally from traditional Sanger sequencing that has been the mainstay for the past several decades. First, and most well-recognized, is the dramatically lower cost of current sequencing methods compared with Sanger sequencing. Costs have dropped by at least 10,000-fold over the past decade. This drop in cost has transformed genome sequencing from the work of an entire community over a decade (the initial sequencing of the human genome took 15 years and ~$3 billion) to a routine experiment done in a matter of weeks at a cost that is projected to drop to as low as $1000 by the end of 2012. These exponential cost reductions have come about not through dramatic drops in reagent costs but rather through dramatic increases in data output. A single lane on a modern sequencer generates vastly more data than a lane of conventional sequencing. This is relevant because to realize the lower costs of contemporary sequencing, large-scale projects must be undertaken. That is, devoting a single lane of sequencing to the sequencing of a plasmid, for example, is *more* expensive with current technologies than with traditional Sanger sequencing; the cost savings are only realized when large data outputs are required (e.g., the sequencing of entire genomes or of isolated genes across large numbers of patients).

Error Rates and Coverage

When executed and analyzed properly, next-generation sequencing technologies can yield nearly perfect fidelity of sequence. At the same time, the error rates for any given sequencing read can be as high as 1%, depending on the sequencing platform. How can these two statements both be correct? Although a 1% error rate (99% accurate) may seem low, when taken in the context of sequencing all 3 billion bases of the human genome, that would in principle result in 30 million errors! Thankfully, this is not the case because most sequencing errors are idiosyncratic—that is, they are not a function of a particular DNA sequence. The consequence of this is that by simply resequencing the same region multiple times and taking the consensus read, such idiosyncratic errors are lost; it is highly unlikely for them to occur over and over again at the same spot.

For normal, diploid genomes, sequencing is typically done 30-fold over (referred to as *30X coverage*). The consensus obtained by observing a given nucleotide 30 times is generally sufficient for rendering the correct read of that nucleotide. However, things get more complicated when dealing with (1) tumors containing gene copy number alterations (e.g., aneuploidy or regions or gene deletion or amplification) or (2) admixture of normal cells within the tumor sample. To compensate for copy number variation and normal cell contamination seen in most samples, typical cancer genome sequencing projects aim for a depth of coverage of at least 100X. Sequencing for diagnostic purposes may require even greater depth of coverage. And the analysis of samples containing only rare tumor cells (e.g., 10%) would require ultra-deep sequencing or any tumor-specific mutations would likely become false-negatives. Importantly, the frequency of cancer-associated mutations in studies performed using traditional Sanger sequencing methods may have been underestimated because of the lack of power to detect mutations in tumors with significant normal cell contamination. Whereas Sanger sequencing delivers the *average* allele observed in a sample, next-generation sequencing methods deliver a *distribution* of observed alleles, allowing for mutant alleles to be identified even if they represent a minority population.

Future of Sequencing Technologies

No one could have predicted the dramatic advances that have come to DNA sequencing technologies over the past several years. Costs have dropped dramatically, and it is predicted that costs will continue to drop, although less precipitously. It is likely that the cost of whole-genome sequencing will drop to $1000 by 2013, and some projections anticipate even further cost reductions. The details are unimportant, but the implications are clear: the cost of genome sequencing will soon shift from sequence *generation* to sequence *analysis*. Although future technologies may allow for the rapid sequencing of entire genomes for hundreds of dollars on a benchtop instrument, the interpretation of the observed sequence variants (whether germline or somatic) will be less obvious. The cost of storage of genome sequence may soon exceed the cost of generating the data in the first place, and a detailed analysis is far from straightforward. Nevertheless, it is likely that over the decade ahead, genome sequencing will become a routine component of both clinical research and routine clinical care.

DNA-LEVEL CHARACTERIZATION

Somatic Versus Germline Events

It is important to recognize the fundamental difference between *germline* variants and *somatic* variants in genome sequence. Germline variants are present in all cells of the body (with the exception of rare mosaicism), and these variants can contribute to the risk of future disease. Germline variants can be common (i.e., seen in ≥5% of the human population), or they can be rare (in principle, unique to a single individual). Each individual also carries 10s of de novo variants that are present in neither of the individual's parents' genome. It remains to be determined to what extent hematologic diseases (whether malignant or otherwise) are caused by germline genetic variation. Although it is clear that certain disorders (e.g., hemophilia) have a highly penetrant, Mendelian basis, it is less certain whether genetic variation explains a significant amount of disease that has been historically considered "sporadic."

In contrast, mutations present in tumors but absent in the normal cells from that individual are referred to as *somatic*. Somatic mutations are thought to be the major drivers of cancer behavior. However, all somatic mutations are not causal *drivers* of cancer. Indeed, the majority of somatic mutations observed in any individual tumor are likely to passenger mutations—that is, they play no functional role in the pathogenesis of the tumor but rather were present in a cell that subsequently acquired a driver mutation that resulted in the cell's clonal outgrowth. The proportion of passengers to drivers likely differs from tumor type to tumor type. For example, tumors associated with tobacco (e.g., lung cancer) or sunlight exposure (e.g., melanoma) have very high mutation frequencies with the majority of the observed mutations being "passengers." In contrast, many hematologic malignancies (e.g., acute myeloid leukemia) have relatively low mutation rates, and some cancers such as infant leukemias have extraordinarily low rates, with only a handful of protein-coding somatic mutations seen per patient.

Distinguishing passenger mutations from driver mutations is a major focus of cancer genome research. It is likely that the complete delineation of the biologically important mutations in cancer will require both large-scale sequencing studies (enabling the identification of recurrent mutations) and the functional characterization of observed mutations.

Point Mutations

The most common type of genetic variants (both germline and somatic) are single nucleotide variants, also known as point mutations. As more individuals are sequenced and deposited into databases, it is becoming possible to catalog all common variations in the human population. Still, it is estimated that every individual will harbor 50 to 100 coding mutations not present in any database. For these reasons, it is particularly important to compare the somatic genome of a tumor with its matched normal germline sequence or else "private" germline variants may be mistaken for somatic mutations.

Certain patterns of point mutation are characteristic of particular environmental exposures. For example, G>T/C>A transversions are characteristic of tobacco-associated lung cancer, and C>T/G>A transitions are characteristic of ultraviolet-associated skin cancers. Most hematologic malignancies lack a particular pattern of mutation, although B-cell lymphomas demonstrate a characteristic pattern of hotspots of mutations caused by activation-induced adenosine deaminase–mediated somatic hypermutation.[12,13]

Although not as common as point mutations, small somatic insertions or deletions (referred to collectively as *indels*) are also observed in tumors. These generally consist of the loss or gain of one or a few nucleotides that, when they occur within protein-coding regions, result in translation frame shifts that generally yield loss-of-function alleles.

Copy Number

Gains (amplifications) or losses (deletions) of genetic material at specific loci are recognized as playing an important role in the pathophysiology of disease. Germline copy number variants have recently been reported, although these are only rarely associated with hematologic disease. Trisomy 21, for example, predisposes to transient myeloproliferative disorders and acute megakaryoblastic leukemia.

Deletions at the RB1 locus encoding the retinoblastoma gene or deletions of the *TP53* gene encoding the p53 tumor suppressor predispose to the development of solid cancers, although only rarely hematologic malignancies. In a landmark set of studies, it was shown that tumors from patients who inherit a mutant copy of the retinoblastoma tumor suppressor gene often contain deletions of the remaining allele.[14] This process has been termed *loss of heterozygosity,* and the search for genetic loci showing loss of heterozygosity in tumor samples has identified a number of genes that are involved in critical cellular processes and are important for cancer progression. Similarly, amplification of genomic loci can play an important role in oncogenesis and cancer biology. For example, amplification of the ERBB2 (HER2) oncogene in human breast cancer predicts a poor prognosis, and ERBB2 has been shown to be an important therapeutic target in this disease.[15]

The search for gains and losses of genetic material can be done using a number of techniques that require various levels of expertise and allow assessment of genomic integrity at various resolutions. The first method developed to assess genomic integrity, *cytogenetic analysis,* is still used today, but it allows identification only of abnormalities that encompass large regions of the genome. Nevertheless, cytogenetic analysis has provided tremendous insight into the pathophysiology of disease, particularly for leukemogenesis.[16] Cytogenetic analysis remains a key part of the diagnostic workup for new cases of leukemia.

More recently developed methods for assessing copy number include *comparative genomic hybridization* (CGH) and high-density single nucleotide polymorphism (SNP) arrays. Although CGH is no longer extensively used, SNP arrays represent a powerful tool for assessing copy number variation. Commonly used SNP arrays contain nearly two million probes, allowing for small copy number aberrations (in some cases reflecting only certain exons of a single gene) to be routinely detected. Lastly, massively parallel genome sequencing can be used for copy number variant detection. The degree to which sequencing can yield as reproducible an assessment of copy number as SNP arrays has yet to be established.

Special note should be made of the analysis of copy number data. At the level of the individual sample (e.g., a tumor), one can easily visualize regions of aberration using tools such as the integrative genomics viewer (IGV) (Fig. 2-2).[17] Although this type of analysis highlights those aberrations in a *particular* sample, it does not reflect copy number abnormalities that are commonly observed across a *collection* of samples. Such recurrent copy number gains or losses tend to indicate biologically important events, as opposed to copy number aberrations that simply reflect genomic instability, but do not contribute to cancer pathogenesis (and therefore are nonrecurrent). To identify statistically significant regions of copy number abnormalities, algorithms such as the GISTIC (genomic identification of significant targets in cancer) method[18] can be applied, yielding a plot of regions of amplification and deletion that are commonly observed in a set of samples (as shown in Fig. 2-3 for 24 patients with multiple myeloma).

Rearrangements

Chromosomal rearrangements (including balanced and unbalanced translocations, inversions, and more complex aberrations) are particularly important in the hematologic malignancies. Translocations were among the very first genomic defects to be discovered in cancer because cytogenetic analysis of metaphase chromosome spreads was feasible for the acute leukemias long before more technically advanced methods become available. Two basic types of translocations are common: those that result in fusion proteins involving two distinct genes and those that result in overexpression of an otherwise structurally normal gene. Translocations resulting in fusion transcripts (e.g., *ETV6/RUNX1* in acute lymphoblastic leukemia)

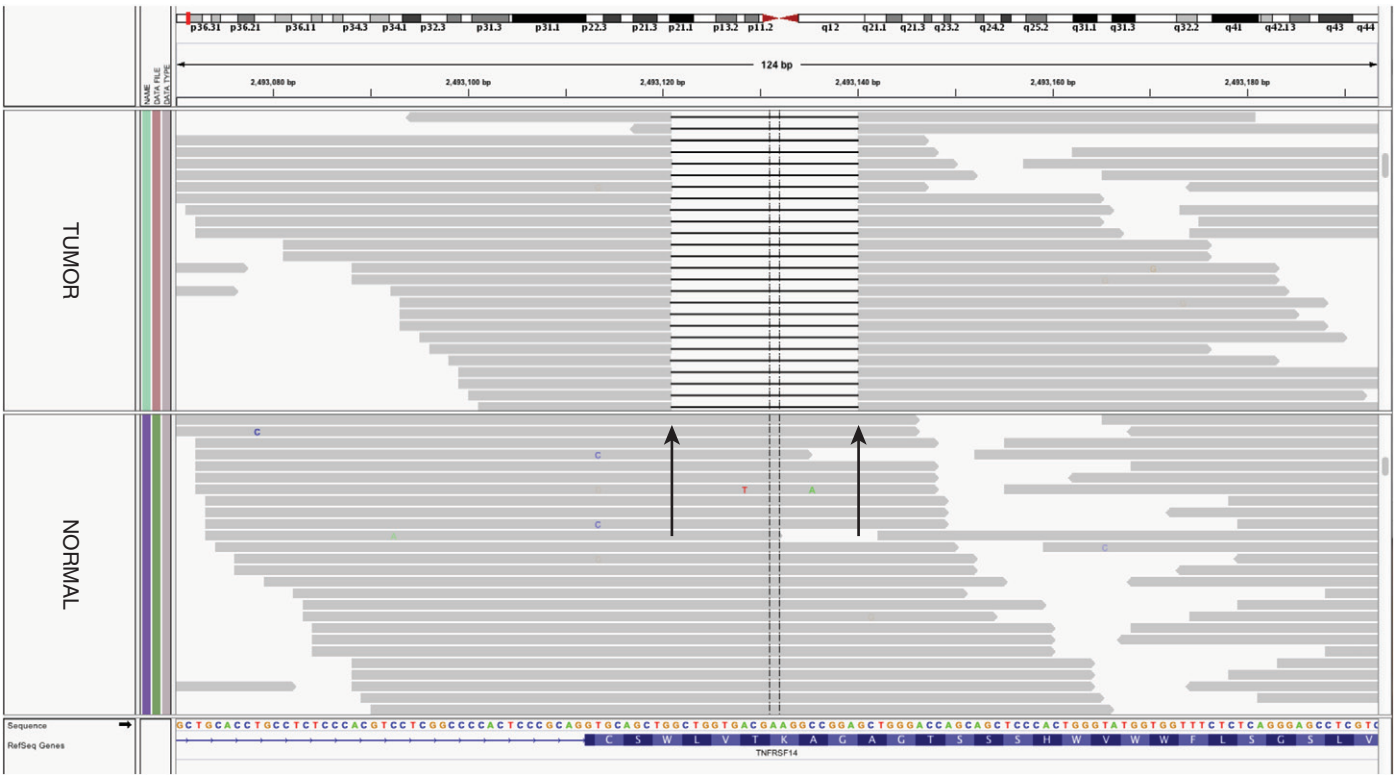

Figure 2-2 GENOME DELETION IN A PATIENT WITH DIFFUSE LARGE B-CELL LYMPHOMA (DLBCL). Genome sequencing of a patient with DLBCL revealed a clear region of genome deletion within the *TNFRS14* gene, as visualized in the integrative genomics viewer (IGV). The *grey bars* indicate the extent of the sequence read, with this region being interrogated multiple times. The *white block* in the middle (bracketed by *red arrows*) indicates the region of genome deletion captured by all of the reads in the tumor but in none of the reads from the matched normal DNA sample (*bottom portion* of figure).

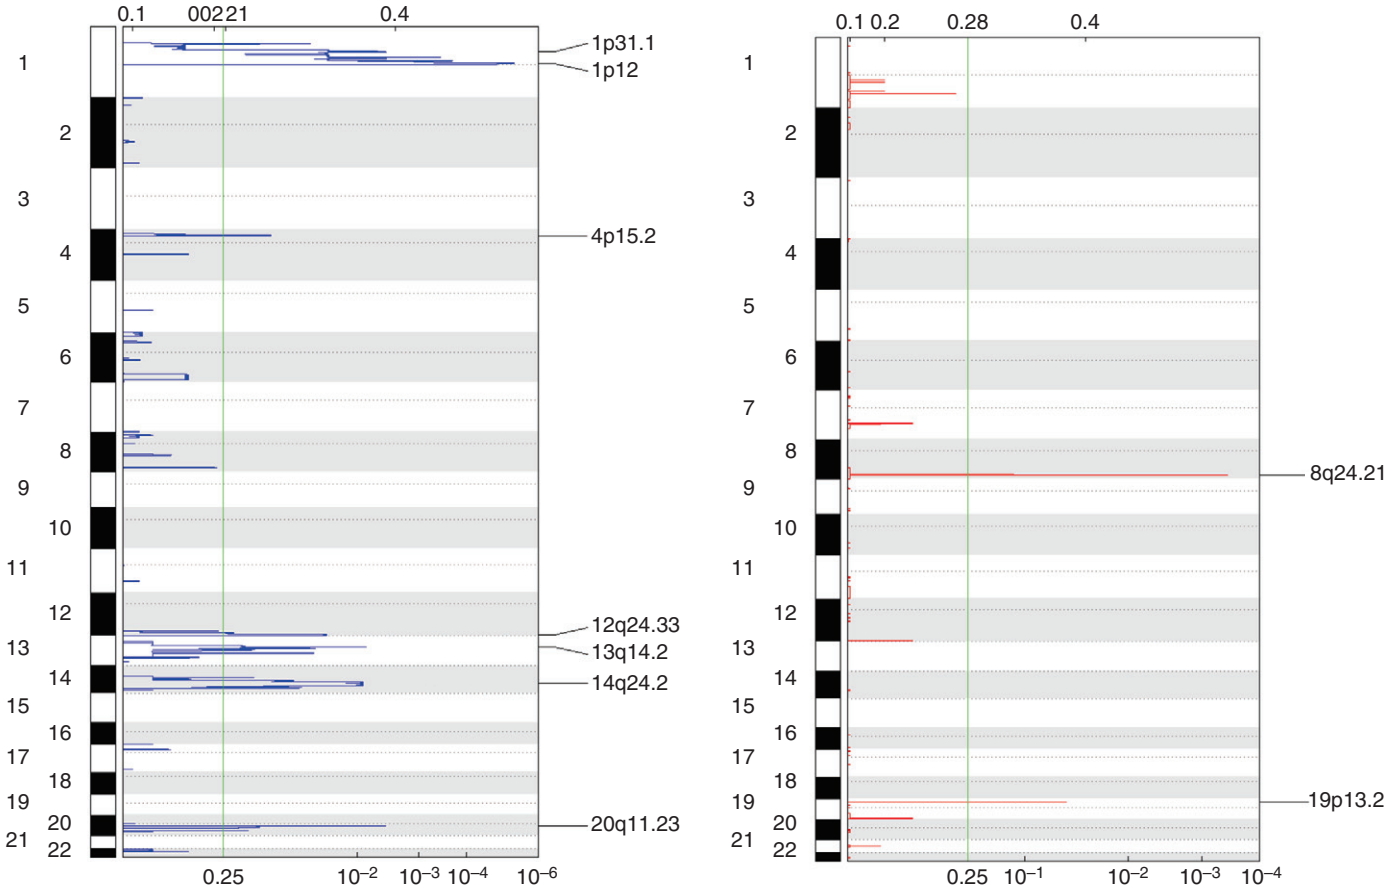

Figure 2-3 RECURRENT COPY NUMBER ABERRATIONS IN MULTIPLE MYELOMA. Output of the GISTIC (genomic identification of significant targets in cancer) algorithm indicates recurrent regions of gene copy number gain and loss. Recurrent gains are shown in *red* (including the *MYC* gene at 8q24), and recurrent losses are shown in *blue* (including the *RB* gene at 13q14). The height of each peak indicates the statistical significance of the event (a function of frequency and the rate expected by chance).

generally involve chromosomal breakage within intronic regions of the two genes, with in-frame fusion a result of the normal process of RNA splicing. In contrast, translocations resulting in overexpression typically involve the juxtaposition of a coding region next to a highly active promoter or enhancer region such as an immunoglobulin region in B cells. For example, in follicular lymphoma, translocations frequently involve juxtaposition of the antiapoptotic gene *BCL2* to the immunoglobulin heavy chain enhancer region, leading to massive overexpression of *BCL2* RNA and protein.

Translocations are best detected by either whole-genome sequencing or RNA sequencing ("RNAseq"), although their detection requires advanced computational analysis to distinguish them from artifactual errors in aligning sequence reads to a reference genome. For reasons that remain unclear, some tumors contain few, if any, translocations, but others contain hundreds, often involving multiple complex rearrangements. A particularly interesting phenomenon, recently termed *chromothripsis,* involves extensive complex genome rearrangements thought to occur via a single "big bang" genomic catastrophe (Fig. 2-4).[19] It has been speculated that chromothripsis may represent a mechanism by which a cell can acquire multiple oncogenic events required for cellular transformation in a single event rather than in a stepwise manner.

Methylation

Although the majority of information encoded in the genome is thought to emanate from its primary DNA sequence, it is clear that additional modifications of DNA play important regulatory roles. For example, DNA methylation can occur, particularly in CpG-rich regions of the genome, and such methylation can lead to the silencing of gene expression at that locus. Although methylation in normal tissues is relatively uncommon, widespread methylation appears frequently in cancer and may serve as an important mechanism of silencing tumor suppressor genes. Until recently, it has not been possible to systematically assess DNA methylation across the genome, but massively parallel sequencing instruments, coupled with bisulfite sequencing approaches, are now paving the way for the first genome-wide assessments of DNA methylation in development and disease. The extent to which aberrant methylation is an important driver of disease (as opposed to simply a reflection of it) remains to be determined.

RNA-LEVEL CHARACTERIZATION

mRNA Profiling

The most well developed and widely used genomic technology is genome-wide expression profiling of protein-coding RNAs (mRNAs). Most such profiling is done using an array format in which sequence-specific probes are immobilized onto a solid surface (or are synthesized in situ); mRNA is isolated from a sample of interest (e.g., a tumor biopsy or a cell line); the mRNA is labeled in some fashion, often with a fluorescent tag; and the extent of hybridization of the mRNA to the array is captured by a laser scanning device. In the early days of arrays, investigators made their own arrays, but at present

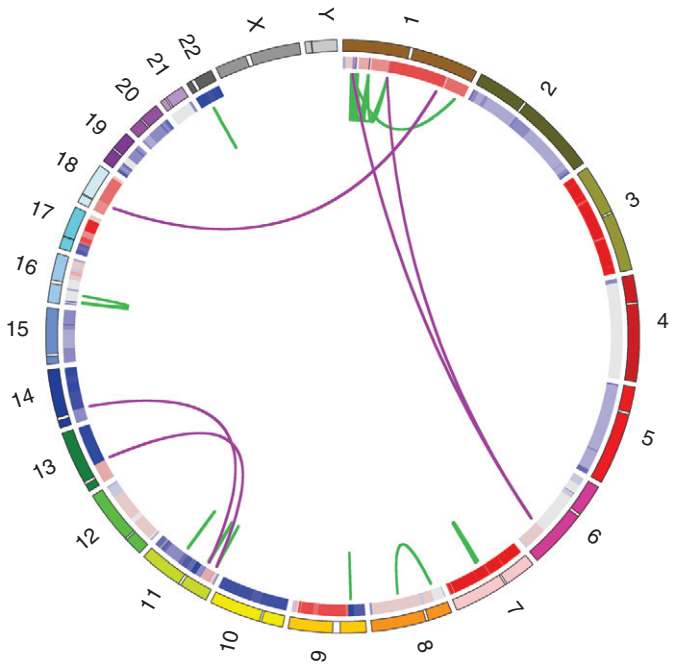

Figure 2-4 CHROMOTHRIPSIS. CIRCOS plot showing the extensive genomic rearrangements in a glioblastoma tumor. Each of the human chromosomes is displayed around the circle of the plot. *Purple lines* indicate rearrangements between different chromosomes, and *green lines* indicate intrachromosomal rearrangements. In this tumor, chromosome 1p has nearly 100 chromosomal rearrangements indicative of a single-step genomic catastrophe mechanism known as chromothripsis.

they are routinely available from a number of sources at high quality and relatively low cost, enabling the interrogation of all 22,000 or so mRNAs in the human and mouse transcriptomes.

Expression-profiling of FFPE tissues deserves special mention. Formalin fixation causes the degradation of mRNAs to fragments of only about 80 nucleotides in length. Conventional array-based profiling approaches therefore do not work well, particularly those that involve labeling of the mRNAs by priming of the 3′ polyadenylation tail. Two promising approaches have been recently developed, however, allowing for the profiling of FFPE-derived tissues. The first is a minor modification of standard arrays involving the use of 3′-biased probes for each mRNA transcript, such that even degraded mRNAs can be profiled. The other approach, known as the c**D**NA-mediated **a**nnealing, **s**election, extension, and **l**igation Method (DASL) method, involves highly multiplexed locus-specific, short PCR reactions.[5] Although it is likely that any method applied to FFPE samples will yield noisier data compared with frozen samples, the ability to analyze archived material, particularly those samples with long-term clinical outcome data, will prove invaluable.

Array-based approaches do not give absolute quantitation, but often this is not required. Rather, researchers wish to compare the expression level of a gene (or genes) in one sample with another (or one group of samples to another). Most gene expression profiling thus requires the *relative* assessment of expression across a set of samples, and absolute quantitation (e.g., number of mRNA copies per cell) is neither possible nor in most cases necessary. More recent sequencing-based approaches to expression profiling ("RNAseq"), however, provide the opportunity to provide a count of the number of transcripts in a given sample. In addition, RNA sequencing allows for the profiling of previously unknown genes (i.e., those not previously recognized to encode a transcript) as well as alternative splice forms of known mRNAs. The extent to which aberrant splicing underlies disease is at this time unknown. Until the advent of RNAseq, there was no way to systematically assess splicing patterns across the genome. The years ahead will likely bring significant new insights into this phenomenon.

Noncoding RNA Profiling

Until very recently, nearly the entirety of focus within the family of RNAs has been on those that code for proteins. However, recent studies have clearly demonstrated that a wealth of noncoding RNAs exist in mammalian cells. Two major classes of noncoding RNAs have been discovered: short RNAs known as *microRNAs* (miRNAs) and *large intergenic noncoding RNAs* (lincRNAs), as described below.

miRNAs are small (≈22 nucleotides) RNAs that do not encode for proteins but bind to mRNA transcripts to regulate translation and mRNA stability. Several hundred miRNAs are thought to exist in the human genome. In *Caenorhabditis elegans,* zebrafish, and other model organisms, miRNAs play a critical role in development through regulation of translation of key proteins. In mammalian cells, a role for miRNAs has been recognized in the regulation of cellular differentiation. Not only are many miRNAs differentially expressed across hematopoietic lineages, but several miRNAs have also been demonstrated to play key functional roles in hematopoietic lineage specification and differentiation.[20] Moreover, the expression or function of several miRNAs is altered by chromosomal translocations, deletions, or mutations in leukemia. In addition, members of the protein complex (including the protein DICER) that process the maturation of miRNAs from longer RNA forms have been implicated in malignancy.

Noncoding lincRNAs range are approximately 1000 nucleotides in length and number approximately 5000 in the human genome. The widespread existence of lincRNAs was only discovered in 2009, and their function remains largely unknown. However, recent evidence suggests that they may play important roles in establishing and maintaining cell fate and may play key roles in regulation of the epigenome. To date, no defects in lincRNAs have been reported in association with hematologic disease, but few, if any, large-scale surveys have been conducted. Their role in the pathogenesis of disease therefore remains unknown. Interestingly, lincRNAs appear to have exquisite tissue-specific patterns of expression, suggesting that they may have future diagnostic potential.

The expression of noncoding RNAs can be performed using hybridization-based arrays similar to those used for standard mRNA profiling. It is likely, however, that as the cost of sequencing continues to fall, comprehensive RNA sequencing will become the platform of choice, yielding in a single experiment the expression of all coding and noncoding RNAs.

PROTEIN-LEVEL CHARACTERIZATION

Unlike the characterization of DNA and RNA, which have become routine, the systematic, genome-wide characterization of proteins remains extremely technically challenging. Not long ago, comparative proteomic experiments largely consisted of the comparison of single proteins across various conditions or samples. However, a number of new advances in technology have made for a dramatic acceleration of the pace at which the abundance of proteins can be measured and their posttranslational modification (e.g., phosphorylation) assessed.

Mass Spectrometry

The workhorse of proteomics remains mass spectrometry. The fundamental principles of mass spectrometry have not changed over the years, but technical advances (the details of which are beyond the scope of this chapter) have led to increased ability to detect proteins in complex mixtures. Previously, extensive biochemical fractionation of the proteome was required to render mixtures of proteins sufficiently limited in number and with sufficient abundance so as to be reliably detected and identified. Such fractionation required extensive time, expertise, instrumentation, and a large amount of starting material, all of which tended to make systematic proteomic experiments difficult to perform routinely. However, newer instruments and

methods allow for the analysis of significantly more complex mixtures. Today it is possible to quantitatively measure proteins and their modification with roughly 20-fold greater sensitivity and fivefold greater speed than just 5 years ago. Sequence assignment confidence, especially for modified peptides, has also been markedly improved owing to the more than 100-fold increase in both resolution and mass accuracy. For example, in mammalian cells, it is now possible to confidently detect more than 8000 unique proteins and more than 15,000 phosphopeptides in a few days on a single instrument. Experts believe that the coming years will bring the ability to perform proteome-wide analysis of complex samples such as entire cells and tissues without extensive fractionation. If this comes to pass, the interrogation of the proteome is likely to become a routine part of biomedical research.

Reverse Phase Lysates

An attractive alternate to mass spectrometry involves the use of *reverse phase lysate arrays* (RPPAs). RPPAs involve the robotic spotting of minute amounts of total cell protein lysates onto glass slides (thus creating an array of lysates from different samples) (Fig. 2-5). The slides can then be probed with antibodies against particular proteins of interest, including phosphorylation-specific antibodies.[21] The advantage of RPPAs is that only a tiny amount of cellular material is required, and hundreds of samples can be tested on a single array. The downside is that the method requires the availability of high-quality antibodies that are both sensitive and specific for the protein of interest. Unfortunately, such high-quality antibodies are available for only a minority of human proteins. In addition, RPPAs are not suitable for the analysis of large numbers of proteins because each protein to be interrogated requires a separate slide. Nevertheless, RPPA remains a powerful new tool in the armamentarium of proteomic research and may prove particularly useful for the comparison of proteins of interest across a large panel of samples (e.g., across a collection of patient samples or cell lines).

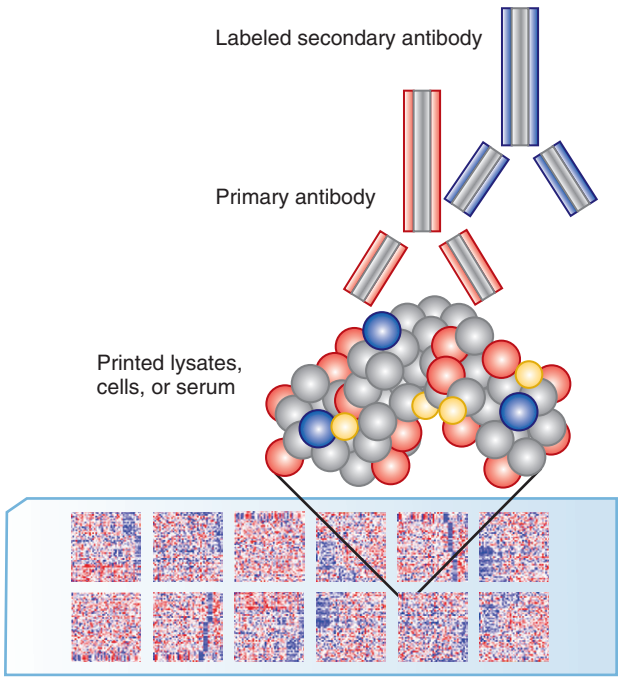

Figure 2-5 REVERSE PHASE PROTEIN ARRAYS (RPPAs). Schematic illustrating the concept of RPPA. Cellular lysates from patient samples or cell lines are robotically spotted onto a glass slide. Next, a primary antibody specific for a protein of interest is added to the slide, with the antibody sticking to the array in proportion to the abundance of the protein in question. To visualize the antibody-binding event, a secondary antibody that recognizes the primary antibody (generally fluorescently labeled) is added, and the slide examined by microscopy or a laser scanning instrument.

Bead-Based Profiling

Another new proteomic method involves the multiplexed analysis of protein abundance or phosphorylation. Phosphorylation involves the use of Luminex microspheres (beads). In this approach, a different protein-specific antibody is coupled to beads of distinct color. A mixture of antibody-coupled beads is then mixed with protein lysate and then binding events are detected with a labeled secondary antibody (e.g., anti-phosphotyrosine antibody). Multiple analytes are thereby simultaneously profiled in a single sample. This approach was successfully used to profile the tyrosine phosphorylation status of nearly all protein tyrosine kinases across a panel of cell lines.[4] The advantage of this approach is that multiple proteins (as many as 100 or more) can be simultaneously assessed in a single sample. But, similar to RPPA, the method depends on the availability of high-quality antibodies, and this limitation makes the approach difficult to generalize broadly. Nevertheless, the method may prove useful for interrogating particular classes of proteins such as kinases, for which suitable antibodies exist.

METABOLITE-LEVEL CHARACTERIZATION

Beyond nucleic acid and protein characterization, systematic profiling of small-molecule metabolites has also recently become possible. Such unbiased approaches to the assessment of metabolite levels have yielded new insights into the pathogenesis of metabolic diseases such as diabetes.[22] In addition, the recent discovery of mutations in metabolic enzymes in acute myeloid leukemia has spurred interest in the metabolic consequences of these mutations on the "metabolome."[23] Metabolite profiling is at present not routinely used in biomedical research, but it is likely that the years ahead will see a significant surge in its use.

FUNCTIONAL GENOMICS

Although the bulk of genomics research takes the form of observational studies (i.e., determining the spectrum of mutations in a tumor), increasingly, functional approaches to genomic research are becoming feasible. For example, the discovery of RNAi technology has now made it possible to knock down the expression of all genes in a given cell line and measure the consequence. This approach has been taken most extensively in the area of cancer, where the complete set of genes that are essential for the survival of a cancer cell line can be identified via genome-wide RNAi screens conduct genome-wide screens (Fig. 2-6). For example, a recent report elucidated the genes required for survival of each of approximately 100 cancer cell lines.[24] Similar approaches have been reported for hematologic malignancies, such as in multiple myeloma, in which new therapeutic targets were suggested.[25] In addition to pointing to new potential therapeutic targets for cancer, large-scale RNAi screens hold the promise of identifying genetic predictors of gene dependency. Such predictors will be key for the translation of these in vitro approaches to the clinic.

In addition to loss-of-function RNAi screens, it is also becoming possible to perform systematic gain-of-function screens by overexpressing a library of cDNAs and then selecting for a phenotype of interest. This approach was recently piloted in the study of drug resistance in melanoma, leading to the discovery of the kinase COT that appears to confer resistance to BRAF inhibitors by providing an alternate path to activating the mitogen-activated protein (MAP) kinase pathway.[26]

Other approaches to functional genomics include various strategies aimed at insertional mutagenesis, whereby endogenous genes in the genome are either activated or inactivated via the ectopic insertion

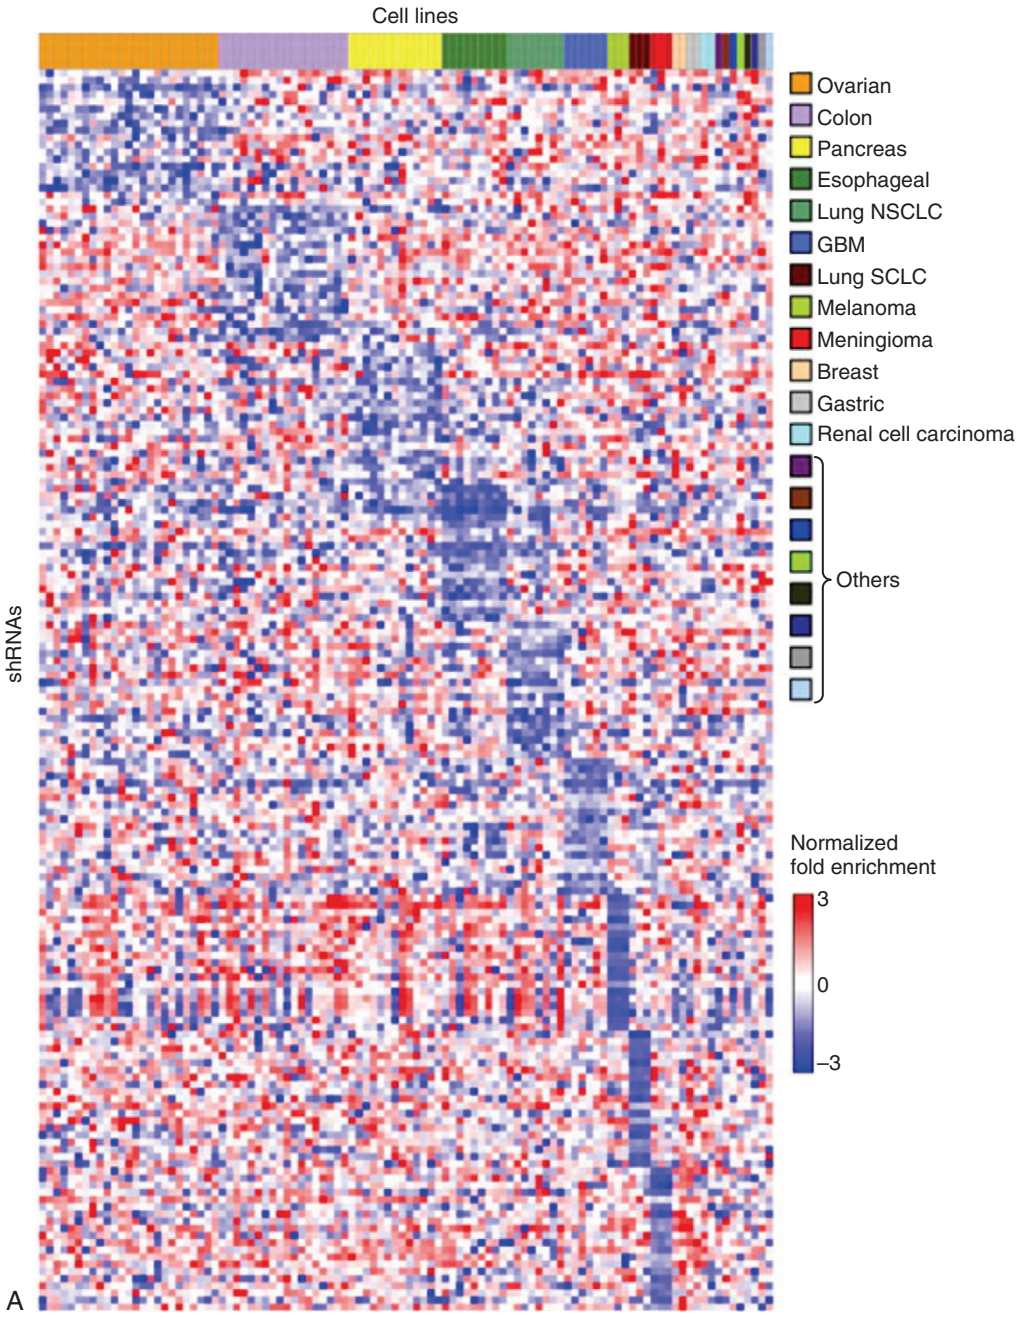

Figure 2-6 SYSTEMATIC RNA INTERFERENCE SCREENS. Lineage-specific dependencies. Heatmap of differentially antiproliferative short hairpin RNAs (shRNAs) in cell lines from individual cancer lineages in comparison with all others. The top 20 shRNAs that distinguish each lineage from the others are displayed. *GBM,* Glioblastoma multiforme; *NSCLC,* non–small cell lung cancer; *SCLC,* small cell lung cancer. *(From Cheung HW, Cowley GS, Weir BA, et al: Systematic investigation of genetic vulnerabilities across cancer cell lines reveals lineage-specific dependencies in ovarian cancer.* Proc Natl Acad Sci U S A *108:12372, 2011.)*

of foreign genetic material such as a transposon. These approaches can be powerful methods of mutagenizing the genome to find functionally important elements. Similarly, random mutagenesis can be performed chemically with agents such as *N*-ethyl N-nitrosourea (ENU).

Last, new and potentially powerful methods for genome engineering have been recently described, whereby transcription activator-like effectors (TALEs) have been used to either modulate transcription or edit the genome sequence at any locus of interest within the genome.[27] This approach may prove particularly useful in the functional testing of disease-associated genetic variants; the ability to experimentally revert a variant allele to its wild-type version should allow for the consequence of the variant to be monitored. This will be essential in establishing the functional role of disease-associated risk alleles identified through genome-wide association studies.

PHARMACOGENOMICS

The use of the genome to study drug response deserves special mention and is the subject of an entire chapter of this book (see Chapter 7). As the cost of genome sequencing continues to fall, it will become increasingly feasible to perform population-scale genetic studies to identify genetic determinants of drug toxicity and response.

Although some examples of such pharmacogenomic markers have been discovered (e.g., genetic predictors of antimetabolite chemotherapy), the field is still in its infancy and awaits truly large-scale, systematic studies of large numbers of patients with known drug response data.

CLINICAL USE OF GENOMICS

Expression-Based Diagnostics

It has been over a decade since the first proof-of-principle studies were published demonstrating the possibility of using gene expression profiling to classify diseases such as cancer. Those studies raised the possibility that such promising gene expression signatures might be further validated and then implemented in the routine clinical setting as powerful diagnostic tests. The reality is that few such transitions to clinical practice have been made. The notable exception to this is the OncoType Dx test, which consists of a tumor gene expression signature of 21 genes capable of determining the requirement for chemotherapy in women with early stage breast cancer. This test has now become part of the standard of care at many cancer centers nationwide.

One should ask, however, why, despite thousands of papers being published on potential diagnostic applications of gene expression profiling, so few have progressed to routine clinical implementation. There are likely several reasons to explain the slow pace of advancement. First, to develop truly valid diagnostic tests, the test must be applied to large numbers of patients with known clinical outcome, and in many cases, such cohorts of patients simply do not exist, making validation challenging. Second, because gene expression signatures are based on relative transcript abundance (as opposed to, for example, genome sequencing), it is subject to technical variation such as stromal admixture of tumors that can distort a diagnostic signature. Third, although the academic publishing system tends to reward *initial* discoveries (which are often published in high-profile journals), the essential follow-up *validation* studies tend to be valued less, and therefore investigators are not incentivized to follow up initial observations. And finally, the economics of molecular diagnostics have in general not been favorable, thereby discouraging companies from making major investments in the validation and commercialization of promising diagnostic tests. It is likely that diagnostic tests will command more of a premium in the future as a mechanism to use expensive therapeutics only in patients likely to benefit, but the time required for this to evolve is uncertain.

Sequencing-Based Diagnostics

With the recent dramatic fall in the cost of genome sequencing has come the prospect of introducing comprehensive sequencing into the clinical setting. Compared with RNA-based analysis, DNA-based diagnostics have the advantage of being more definitive in that one is looking, for example, for the presence of a mutation (an A, G, C, or T) as opposed to a relative abundance of a particular transcript or transcripts. Also, because modern sequencing approaches allow for allele separation, the admixture of tumors with normal cells can be overcome simply by increasing depth of sequencing coverage, as described in the preceding sections. Therefore, it is likely that in the years ahead, we will see an explosion of sequencing-based diagnostic applications for cancers, including hematologic malignancies, whereby clinically actionable mutations will be assessed by sequencing a panel of genes (hundreds of candidate genes). As the cost of sequencing continues to drop, this will likely give way to more systematic approaches that include whole-exome sequencing and whole-genome sequencing. It is likely, however, that the pace of technology advancement will outstrip our understanding of clinical utility and financial reimbursement by health insurance payers, so the rate at which sequencing-based diagnostics will become mainstream remains to be established.

Sequencing-based diagnostics will also likely have an increasingly important role in nonmalignant conditions, such as blood clotting disorders, in which it will become possible to systematically resequence all genes in the coagulation cascade, thereby identifying either common or highly rare sequence variants that might explain or predict disease. The widespread use of germline sequencing to predict disease also raises a large set of ethical questions that must be addressed in the years ahead, particularly those relating to children and family members of individuals undergoing sequence analysis. Whether whole-genome sequencing will become a routine part of routine health care in the future remains to be determined, but it is almost certain that much of our current diagnostic approach to medicine will eventually be supplanted by DNA-level analysis.

FUTURE DIRECTIONS

The field of genomics has matured greatly over the past decade. Major analytical advances have made it possible to analyze and interpret complex datasets beyond what was previously possible. And dropping costs have made it possible to generate data at a scale that was never before imaginable. For example, it is likely that by the year 2015, there will be more than 100,000 tumor genomes available for analysis to the research community (the first such genome sequence became available only in 2008). We will also witness an explosion of functional genomic studies involving, for example, the genome-wide interrogation of gene dependencies across as many as 1000 cancer cell lines. Each of these approaches, although powerful, has its own limitations, and it is likely that most progress will be made by integrating across many disparate experimental strategies and datasets. The implication of this is that researchers will increasingly need strong quantitative analytical skills to be successful in modern biomedical research. Last, as costs drop and our knowledge base increases, so too will diagnostic opportunities increase. The integration of such genomic approaches into clinical research and routine clinical care is likely to be one of the greatest challenges and opportunities in medicine in the decade ahead.

CHAPTER 3

REGULATION OF GENE EXPRESSION, TRANSCRIPTION, SPLICING, AND RNA METABOLISM

Christopher R. Cogle, Amy Meacham, and Robert A. Hromas

The function of a cell is governed by the sum of the specific proteins expressed. Protein expression is most commonly regulated at the level of gene transcription into ribonucleic acid (RNA), which is then processed and translated. The life of a cell is the life of its RNA. Therefore, to understand how a cell behaves, one must understand the expression of a gene through RNA.

Transcription of deoxyribonucleic acid (DNA) into RNA controls cellular differentiation, proliferation, and apoptosis in all differentiating cell systems, but especially in hematopoiesis. For example, through regulation of transcription, hematopoietic stem cells maintain a balance between quiescence and differentiation to mature blood cell types. Regulation of transcription is also necessary for erythroid progenitors to produce vast quantities of hemoglobin, for myeloid cells to generate granules of immune responses, for lymphocytes to control immunoglobulin levels, and for platelets to regulate levels of thrombotic receptors.

Aberrant gene expression can result in hematologic disorders such as lymphomas, leukemias, and myelodysplastic and myeloproliferative syndromes, as will be discussed later. Understanding the process behind RNA synthesis is also crucial for the diagnosis and treatment of hematologic disorders. Converting genetic information contained in the DNA sequence of a gene into a finished protein product is a complex process consisting of several steps, with each step involving distinct regulatory mechanisms. Beginning with the basics of gene structure, this chapter will present the foundation necessary to understand the process of gene expression through RNA synthesis and processing, including transcription, splicing, posttranscriptional modification, and nuclear export. Subsequent chapters will present regulation of protein translation and posttranslational modifications.

The first step of gene expression is transcription, where RNA polymerases decode the DNA using specific start and stop signals to synthesize RNA. In the subsequent step, splicing removes portions of the RNA that do not code for protein. Next, the spliced RNA is modified for export out of the nucleus and into the cytoplasm, where ribosomes translate RNA into protein products.

HOW GENES ARE ORGANIZED IN DNA

The gene is the fundamental unit for storage and expression of genetic information. Genes are made up of nucleotide sequences of DNA and are transferred to daughter cells during mitosis (and meiosis in gametes) via semiconservative replication. Each cell in the human body contains about 25,000 genes, which are distributed unevenly across the 46 individual chromosomes found within the nucleus. Chromosomes are dense DNA-protein complexes that are made up of individual linear DNA helices packed tightly together by specific protein repeats. Unwound completely and stretched out, the largest chromosome is about one meter in length, demonstrating that the cell, even to exist, must be an expert at packaging.

Only 1% to 2% of human DNA actually serves as genes, which are the templates for protein production. Most genes are broken down into separated coding sections known as *exons* (Fig. 3-1). These exons are separated from each other by intervening, noncoding sequences known as *introns*. Genes also have other noncoding DNA, typically short sequences near or within genes that function as regulatory sequences critical for controlling gene expression. Together, these regulatory sequences determine in which cell, at what time, and in what amount the gene is converted into the corresponding protein.

In order for transcription to begin, RNA polymerase must attach to a specific DNA region at the beginning of a gene. These regions, known as *promoters*, contain specific nucleotide sequences and response elements. These provide a secure initial binding site on the gene for RNA polymerase. RNA polymerase often requires other proteins called *transcription factors* for proper recruitment to a given gene. Not all transcription factors are activating; some may inhibit RNA polymerase and repress gene expression by attaching to specific promoters and blocking binding of RNA polymerase. Promoters can additionally function together with other more distant regulatory DNA regions (termed *enhancers, silencers, boundary elements,* or *insulators*) to direct the level of transcription of a given gene. Unlike RNA polymerase, transcription factors are not limited to the promoter region but can be directed by these other regulatory DNA sequences to either promote or repress transcription. The minimum essential transcription factors needed for transcription to occur are termed *basal transcription factors,* and they include transcription factor IIA (TFIIA), as well as TFIIB, TFIID, TFIIE, TFIIF, and TFIIH. These ubiquitous proteins bind to the recognition sequence in the promoter, forming a transcription initiation complex that recruits the RNA polymerase. Basal transcription factors cannot by themselves increase or decrease the rate of transcription but may be linked to activators by coactivator proteins that can.

The promoter is a regulatory sequence located near the start of the gene, to provide the exact start site recognized by the transcription machinery where conversion of the DNA template into intermediary molecules begins. The promoter contains the consensus sequence to bind the transcription factors and then RNA polymerase needed to initiate transcription. The best-known example of this sequence is the TATA box sequence, TATAAA, which binds RNA polymerase and associated transcription factors. However, more than 80% of mammalian protein-coding genes are driven by TATA-less promoters, which contain different recognition sequences—often GC boxes. The GC promoters are repeats of guanine and cytosine nucleotides, frequently have multiple transcriptional start sites, and require alternative transcription factors, such as specificity protein 1 (Sp1).

Genes can have more than one promoter. This results in different sized mRNAs, depending on how far the promoter is from the 5′ end of the gene. The binding strength between a promoter and the transcription factors determines the avidity of RNA polymerase binding and, subsequently, of transcription. Some genetic diseases are associated with mutations in promoters, such as β-thalassemia, which can involve single nucleotide substitutions, small deletions, or insertions, in the β-globin promoter sequence. The promoter mutations in β-thalassemias result in decreased RNA polymerase binding to the transcriptional start site and thereby reduce β-globin gene expression.

Globin gene expression in erythroid cells is also dependent on another regulatory unit: the enhancer. Unlike promoters, which are

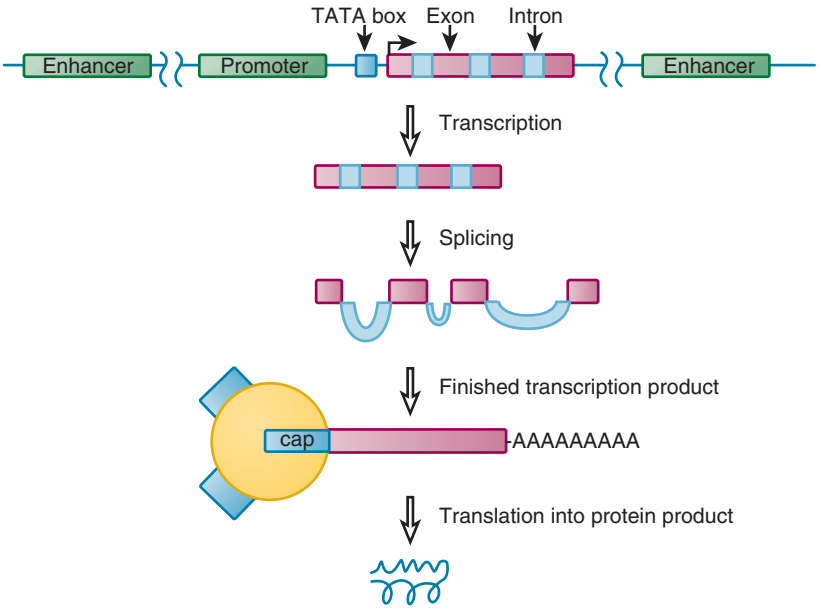

Figure 3-1 OVERVIEW OF GENE TRANSCRIPTION FROM DNA TO RNA AND THEN TRANSLATION FROM RNA TO PROTEIN. Protein synthesis requires multiple processes and regulatory steps including transcript of DNA into RNA, splicing and post-transcription modification of RNA, translation of RNA into protein, and post-translational protein modification.

situated close to the start site of the gene, enhancers can be positioned far to either side of the gene, or even within it. This means that there may be several signals determining whether a certain gene can be transcribed. In fact, multiple enhancer sites may be linked to one gene, and each enhancer may be bound by more than one transcription factor. The determining factor in whether or not such a gene is transcribed is the sum of the activity of these transcription factors bound to the different enhancers. Enhancers can compensate for a weak promoter by binding activator transcription factors. For instance, regulation of gene expression during T-lymphocyte differentiation requires multiple activating transcription factors, such as lymphocyte enhancer factor (LEF1), GATA3, and ETS1, binding to the T-cell receptor alpha (TCRA) gene enhancer.

Transcription factors can also influence multiple genes in coordination, like the globin family. Enhancers are often the major determinant of transcription of developmental genes in the differing lineages and stages of hematopoiesis. They can also inhibit transcription of specific genes in one cell type while, at the same time, activating it in another cell type. When gene sequences routinely negatively regulate gene transcription, they are termed *silencers*. Insulators, another type of DNA regulatory sequence, define borders of multigene clusters to prevent activation of one set of genes from affecting a nearby set of genes in another cluster.

TRANSCRIPTION OF GENES

The first phase of gene expression occurs when the RNA polymerase synthesizes RNA from a DNA gene template. As described in the previous section, this is called *transcription*. The encoded material on the transcribed gene determines the kind of RNA synthesized. For example, proteins are coded for by messenger RNA (mRNA), which will later undergo the process of translation. Alternatively, the transcribed gene may encode transfer RNA (tRNA), which carries specific amino acids to the ribosome for incorporation into the growing protein chain during translation. Another type of RNA synthesized from genes in DNA is ribosomal RNA (rRNA), which serves as the backbone of ribosomes and interacts with tRNA during translation. Ribosomes catalyze the formation of proteins, using the mRNA as the code and the tRNA to obtain the amino acids to build the proteins. Each amino acid is attached to the previous one by hydrolysis and aminotransferase activity residing within the ribosome. Transcription of the different classes of RNAs in eukaryotes is carried out by three different RNA polymerase enzymes. RNA polymerase I (i.e., Pol I) synthesizes the rRNAs, except for the 5S species. RNA polymerase II (i.e., Pol II) synthesizes the mRNAs and some small nuclear RNAs (snRNAs) involved in RNA splicing. RNA polymerase III (i.e., Pol III) synthesizes the 5S rRNA and the tRNAs.

The most intricate controls of eukaryotic genes are those that govern the expression of RNA Pol II-transcribed genes, the genes that encode mRNA. Most eukaryotic mRNA genes contain a basic structure consisting of alternating coding exons and noncoding introns and have one of two major types of basal promoters as defined earlier. These protein-coding genes also can have a variety of transcriptional regulatory domains, such as the enhancers or silencers mentioned earlier. In addition to management of gene expression by the RNA polymerase binding strength of the promoters at the beginning of a given gene, the interaction between activator and inhibitor transcription factor proteins binding to the given promoter also exerts regulatory action on transcription.

To initiate transcription, the RNA polymerase must bind to the promoter sequence. However, as mentioned earlier, this can only happen with help from gene-specific transcription factors that mediate RNA polymerase binding to the promoter. These transcription factors are sequence-specific DNA binding proteins that can be modified by cell signals. Many transcription factors, such as STAT proteins, require phosphorylation in order to bind DNA. Because transcription factors can be targeted by kinases and phosphatases, phosphorylation can effectively integrate information carried by multiple signal transduction pathways, thus providing versatility and flexibility in gene regulation. For example, the Janus kinase (JAK) signal transducer and activator of transcription (STAT) pathway is widely used by members of the cytokine receptor superfamily, including those for granulocyte colony-stimulating factor (G-CSF), erythropoietin, thrombopoietin, interferons, and interleukins. Normally, ligand-bound growth factor receptors lead to JAK2 phosphorylation, which then activates STAT, also by phosphorylation. Activated STAT then dimerizes, translocates to the hematopoietic cell nucleus, binds DNA, and promotes transcription of genes for hematopoiesis. Alteration of JAK2, such as a V617F mutation, results in a constitutively active kinase capable of driving STAT activation. This leads to constitutive transcription of STAT target genes and results in myeloproliferative disorders such as polycythemia vera.

Mutations in promoter sequences that result in decreased transcription factor binding, and therefore less RNA polymerase binding, result in decreased gene expression. One of the best examples of a mutation in a transcription factor binding site associated with a human disease is in the factor IX gene. The transcription factor HNF4α is required to bind to the factor IX promoter before this gene can be transcribed. Patients with a mutation in the HNF4α

binding site can develop hemophilia B, an X-linked recessive bleeding disorder primarily affecting males (Fig. 3-2).

The ability of transcription factors and RNA polymerases to access specific promoters and transcribe genes is also regulated by the packaging of DNA into discrete packets by proteins generically termed *chromatin*. Chromatin can package DNA tightly or loosely, and this regulates the availability of a gene for transcription. Several factors affect the openness of chromatin and therefore regulate availability of the DNA to transcription factors and RNA polymerases. There are two types of chromatin: euchromatin and heterochromatin. *Euchromatin* refers to loosely packaged DNA, where RNA polymerases can freely bind to DNA and genes are actively transcribed. *Heterochromatin* refers to tightly packaged DNA that is protected from transcription machinery, sequestering genes away from transcription. The basic unit of chromatin is the nucleosome, which contains eight histone proteins packaging 146 base pairs of DNA wound 1.7 times around the histone complex (Fig. 3-3).

These histones can be extensively modified to regulate the accessibility of the DNA to the transcriptional apparatus. Histones can be chemically modified by acetylation, methylation, or phosphorylation. In general, acetylation opens the nucleosome to increase transcription, whereas phosphorylation marks damaged DNA. Histone methylation can either open chromatin to increase transcription or close it to repress transcription, depending on where the histone is methylated. Transcription factors can themselves recruit histone-modifying enzymes that can regulate transcription. In hematopoiesis, transcription factors, including GATA1, ELKF, NF-E2, and PU.1, recruit histone acetyltransferases (HATs) and histone deacetylases (HDACs) to promoters of target genes, leading to addition or subtraction of acetyl groups from histones, thereby affecting chromatin structure and the openness of DNA to transcription. A gene essential to erythroid maturation and survival—GATA1, for instance—directly recruits HAT complexes to the β-globin locus to stimulate transcription activation.

Chromatin usually tightly packages DNA, which is essential for the cell to have a functional size and shape. Therefore, for transcription to take place, the DNA must be unwound from the chromatin. This process of unpackaging, called *chromatin remodeling*, is mediated by a family of proteins with switch/sucrose nonfermentable (SWI/SNF) domains. These proteins use ATP hydrolysis to shift the nucleosome core along the length of the DNA, a process also known as *nucleosome sliding*. By sliding nucleosomes away from a gene sequence, SWI/SNF complexes can activate gene transcription.

SWI/SNF proteins also contain helicase enzyme activity, which unwinds the DNA by breaking hydrogen bonds between the complementary nucleotides on opposite strands. By unwinding the DNA into two single strands, the DNA can then be read by RNA polymerases in the direction 3′ to 5′. A new antiparallel RNA strand, 5′

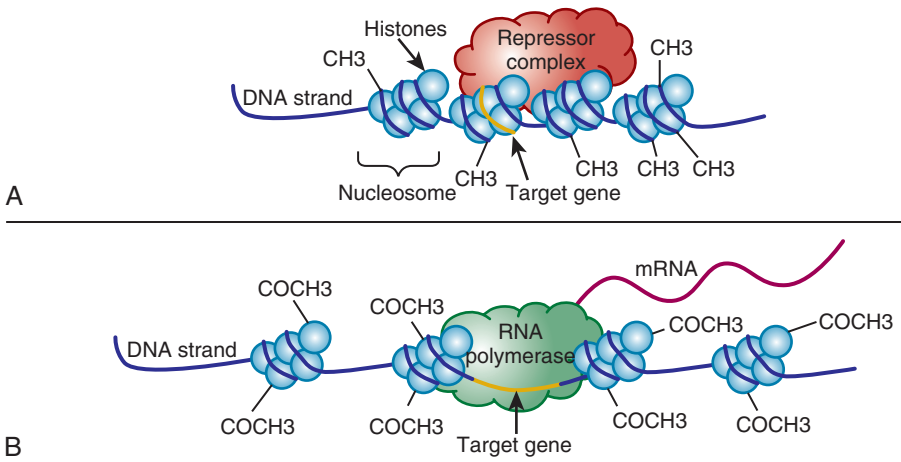

Figure 3-3 CHROMATIN STRUCTURE. **A,** The nucleosome is the fundamental unit of chromatin and is made up of DNA coiled around histone proteins. In a condensed state, the DNA is tightly wrapped around histone complexes and target genes are inaccessible to transcription machinery. **B,** Histones and DNA can be epigenetically modified by acetylation and methylation, rendering the target genes more accessible to transcription machinery.

to 3′, is produced by RNA polymerases to mirror the coding strand of the DNA, with the exception of all thymine nucleotides replaced by uracil nucleotides.

DNA itself can be chemically modified to amplify or suppress transcription. Stretches of cytosine and guanine repeats (i.e., CpG sites because of the single phosphate linking these to nucleotides) in promoters can be chemically modified by methylation enzymes such as DNA methyltransferases (DNMTs), which subsequently alter binding of RNA polymerase and associated transcription factors. Hypermethylation, which blocks DNA transcription and results in gene silencing, has been observed in bone marrow cells of patients with myelodysplastic syndromes (MDS), with the degree of DNA hypermethylation correlating to disease stage. In MDS the promoters of genes that are important for myeloid differentiation are hypermethylated, repressing their transcription and inhibiting proper maturation of the myeloid lineages. Hypomethylating agents such as azacitidine and decitabine can induce remission and prolonged survival in MDS patients. The regulation of gene expression by such chemical modifications of chromatin or DNA itself is referred to as *epigenetic*, since the alteration of cell function results from changes outside of the DNA sequence.

Such epigenetic modifications are crucial to the behavior of hematologic diseases. Mutation of the DNMT3 genes may have indirect effects on gene expression without altered DNA methylation, as have been observed in 20% of acute myeloid leukemia (AML) cases and correlated with poor clinical outcome. The Ten-Eleven-Translocation oncogene member TET2, which plays a role in DNA methylation, and therefore epigenetic stability, is mutated in AML, MDS, chronic myelomonocytic leukemia (CMML), and other myeloproliferative neoplasms (MPNs). Another recurring observation in hematologic malignancies is aberrant histone methylation, for example, at H3K27, seen in myelodysplasia. This is associated with altered gene expression affecting cell cycle, cell death, and cell adhesion pathways.

Before a final mRNA product is made, several proofreading regulatory steps must take place. The RNA polymerase may not even clear the promoter, in which case it will slip off, producing truncated transcripts. Once the transcript reaches approximately 23 nucleotides, the RNA polymerase no longer slips off, and full transcript elongation can occur. RNA polymerase then continues to traverse the template DNA strand, using ATP while complementarily pairing bases and forming the phosphodiester-ribose backbone. Many RNA transcripts may be rapidly produced from a single copy of a gene, as multiple RNA polymerases may transcribe the gene simultaneously, spaced out from one another. An important proofreading mechanism during elongation allows the substitution of incorrectly incorporated bases, usually by permitting short pauses during which the appropriate RNA editing factors can bind. RNA editing mechanisms in mRNAs include nucleoside modifications of cytidine to uridine (C-U) and adenosine to inosine (A-I) by deamination, as well as nucleotide insertions and additions without a DNA template by proteins called *editosomes*.

Another repair mechanism is transcription-coupled nucleotide excision repair, in which RNA polymerase stops transcribing when it comes to a bulky lesion in one of the nucleotides in the gene. A large protein complex excises the DNA segment containing the bulky lesion, and a new DNA segment is synthesized to replace it, using the opposite strand as a template. Then the RNA polymerase resumes transcribing the gene. However, in general, RNA proofreading mechanisms are not as effective as those in DNA replication, and transcription fidelity is lower.

After a gene is transcribed, mRNA is modified to protect it and target it for translation to protein. These modifications include *capping* and *polyadenylation*. Capping occurs shortly after the start of transcription, when a modified guanine nucleotide is added to the 5′ end of the mRNA. This terminal 7-methylguanosine residue is necessary for proper attachment to the ribosome during translation. It also protects the RNA from endogenous ribonucleases that degrade uncapped RNA, which is often viral in origin.

RNA polymerases do not terminate transcription in an orderly manner. They tend to be processive; yet the cell cannot tolerate a population of mRNAs that are enormous in size. Therefore mRNAs have a signal, the sequence AAUAA, that defines the end of the transcript. Ribonucleases cut mRNAs shortly after that signal, and a chain of several hundred adenosine residues is added to that free 3′ transcript end. Synthesis of this poly(A) tail and termination of transcription requires binding of specific proteins, including cleavage/polyadenylation specificity factor (CPSF), cleavage stimulation factor (CstF), polyadenylate polymerase (PAP), polyadenylate binding protein 2 (PAB2), cleavage factor I (CFI) and cleavage factor II (CFII), that function to catalyze cleavage, and to protect the mRNA from exoribonucleases. The poly(A) tail also assists in export of the mRNA from the nucleus, as well as translation. Mutations in the poly(A) signal can result in hematologic disease. For example, some thrombophilic patients have a mutation in the polyadenylation signal in the prothrombin gene, which increases the stabilization of this mRNA, resulting in higher prothrombin protein levels and increased thrombosis.

RNA SPLICING

Before the mRNA can be translated into protein, introns must be removed and the exons re-connected (Fig. 3-4). This process, termed *splicing*, requires a series of reactions mediated by the spliceosome, a complex of small nuclear ribonucleoproteins (snRNPs). The types of snRNPs in the spliceosome determine the mechanism of splicing. Canonical splicing, also called the *lariat pathway*, utilizes the major spliceosome and accounts for more than 99% of splicing. The major spliceosome is composed of the nuclear active snRNPs U1, U2, U4, U5, and U6, along with specific accessory proteins, U2AF and SF1. This complex recognizes the dinucleotide GU at the 5′ end of an intron and an AG at the 3′ end. Intermediately, a lariat structure forms, connecting these ends, providing for both excision of the intron and proper alignment of the ends of the two bordering exons to allow precise ligation. When the intronic flanking sequences do not follow the GU-AG rule, noncanonical splicing removes these rare introns with different splice site sequences using the minor spliceosome. The same U5 snRNP is found in the minor spliceosome, in addition to the unique yet functionally similar U11, U12, U4atac, and U6atac. Furthermore, there are splicing mechanisms, including tRNA splicing and self-splicing, that function without any spliceosome.

Splicing is central to proper gene expression and is therefore required for appropriate hematopoietic development. One of the best

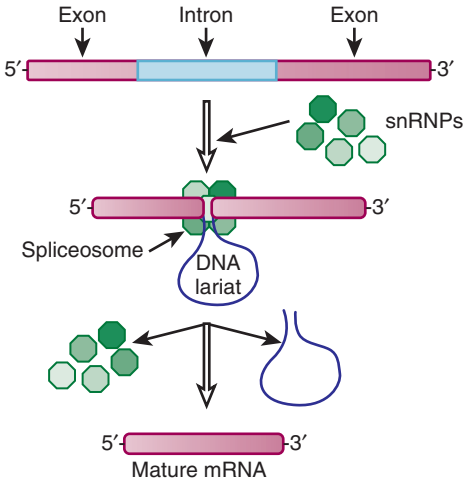

Figure 3-4 RNA SPLICING. Introns from pre-mRNA are removed by small nuclear ribonucleoproteins (snRNPs), which form a protein complex called a *spliceosome*. The spliceosome loops introns into a lariat, excises them, and then joins exons. The mature mRNA is then ready for further posttranscription processing.

examples of inappropriate splicing leading to hematologic disease is β-thalassemia, in which there are a number of different mutations that occur in the GU-AG splicing signals, resulting in aberrant β-globin mRNAs. Abnormal splicing can also lead to AML. The translocation liposarcoma (TLS) protein recruits splicing complexes to mRNAs, and it is involved in the TLS-ERG fusion oncogene in t(16;21) in AML. This fusion of TLS with the transcription factor ERG alters the splicing profile of immature myeloid cells, blocking the expression of genes required for proper differentiation and resulting in accumulation of immature myeloid cell precursor cells. Recently, whole exome sequencing of MDS specimens led to the discovery of frequently occurring mutations in RNA splicing machinery, including U2AF35, ZRSR2, SRSF2 and SF3B1. These results suggest the possibility of aberrant splicing in the pathogenesis of MDS and highlight new targets for treatment.

Trans-splicing is a form of splicing that joins two exons that are not within the same mRNA transcript. Some trans-splicing events occur when the intron splice donor sites are not filled by spliceosomes. They can lead to mRNAs displaying exon repetitions or chimeric fusion RNAs, which can mimic the presence of a chromosomal translocation in normal cells. For example, specific chimeric fusion mRNAs seen in acute leukemias (such as MLL-AF4, BCR-ABL, TEL-AML1, AML1-ETO, PML-RAR, NPM-ALK, and ATIC-ALK) have been found in blood cells from healthy individuals with normal chromosome karyotype. Of interest, these individuals do not develop leukemia, indicating that these fusion oncoproteins must be heritable (in DNA) and that they must occur in the appropriate hematopoietic precursor cell for leukemogenesis.

Alternative splicing can enhance the versatility and diversity of a single gene. By alternatively excising different introns along with the intervening exons, a wide range of unique proteins of differing sizes can be generated. These alternative proteins, termed *isoforms*, come from one gene that generates a variety of mRNA with varying exon composition. Alternative splicing is common and is essential for the proper function of almost all hematopoietic cells. For example, B cells are able to produce both immunoglobulin M (IgM) and immunoglobulin D (IgD) at the same developmental stage using alternative splicing. Additionally, erythrocytes use alternative splicing to produce differing isoforms of cytoskeletal proteins. However, alternative splicing does not always give beneficial results. The mutations in the splicing signals in β-globin gene, mentioned earlier for β-thalassemia, result in abnormal alternative splicing. In addition, in patients with chronic myeloid leukemia (CML), resistance to tyrosine kinase inhibitor therapy has been linked to alternative splicing of the BCR-ABL transcript.

NUCLEAR EXPORT OF RNA

The nuclear envelope serves as a major regulator of gene expression by controlling the flow of RNA to the cytoplasm for translation. Nuclear pore complexes (NPCs) inserted within the nuclear envelope regulate the transport of molecules in and out of the nucleus. Ions, small metabolites, and proteins under 40 kilodaltons (kDa) passively diffuse across NPC channels. However, larger proteins and mRNA are transported through NPCs via energy-dependent (as with guanosine triphosphate [GTP]) and signal-mediated processes that require chaperoning transport proteins.

NPCs are composed of three major parts: (1) a central core containing a 10-nm channel, (2) a nuclear basket that can dilate in response to large cargoes, and (3) flexible fibrils that extend from the central core into the cytoplasm (Fig. 3-5). These large NPCs are composed of nucleoporins, or Nups. Demonstrating how crucial nuclear export of mRNA is for correct hematopoietic development, mutations or deletions in Nups can result in MDS and leukemia. For example, point mutations of Nup98 in hematopoietic precursors results in myelodysplasia and eventual AML. Furthermore, multiple translocations involving Nup98 (up to 29 recognized partners) have been found in patients with MDS and AML as the sole cytogenetic abnormality.

Naked RNA cannot be exported through NPC channels. Rather, RNA export from the nucleus requires that newly synthesized RNAs undergo the previously described processing steps, 5′ capping, splicing, and 3′ polyadenylation. In addition, RNA binding proteins are required to fold and shuttle the modified RNA through NPCs. Several of these RNA-binding proteins have been identified as important in hematopoiesis. For example, the eukaryotic translation initiation factor 4E (eIF4E) enhances nuclear export of specific RNA transcripts and is critical for proper granulocyte differentiation. Overexpression of eIF4E impedes myeloid maturation and can result in AML. Inhibiting eIF4E with ribavirin has shown activity in early-phase clinical trials of AML and may represent a promising novel class of leukemia therapy.

RNA METABOLISM

RNA does not live forever, and that is a good thing. In mammalian cells, mRNA lifetimes range from several minutes to days. The limited lifetime of mRNA enables a cell to alter protein synthesis in response to its changing needs. The stability of mRNA is regulated by the untranslated regions (UTRs) of mRNA. UTRs are sections of the mRNA before the start codon (5′) and after the stop codon (3′) that are not translated. These regions govern mRNA half-life, localization, and translational efficiency. Translational efficiency, both enhancement and inhibition, can be controlled by UTRs. Both proteins and small RNA species can bind to either the 5′ or 3′ UTRs, and these can either regulate translation or influence survival of the transcript. There are several fascinating mechanisms by which this occurs, and these will be described later. UTR sequence regulation of mRNA survival is essential for proper hematopoietic differentiation. The best example of this is globin synthesis, in which its mRNA is quite stable because of UTR sequences. This long half-life meets the needs of reticulocytes to synthesize globin for up to 2 days after terminally mature erythroblasts lose the ability to make new mRNA.

Some of the elements contained in UTRs form a characteristic secondary structure that alters the survival of the mRNA transcript. Riboswitches, one class of these mRNA elements, can sense the concentration of what the mRNA codes for and can alter mRNA survival. For example, the mRNA for several enzymes in the cobalamine pathway have riboswitches that bind adenosylcobalamine, and this regulates the survival of these mRNAs. Thus in states of high cobalamine, riboswitches sense the high cobalamine concentration and decrease survival of the mRNA for enzymes used in this synthetic pathway.

Another class of UTR secondary structures that regulate stability is exemplified by the prothrombin 3′ UTR. This mRNA is constitutively polyadenylated at seven or more positions, and the 3′ UTR is folded into at least two distinct stem-loop conformations. These alternate structures expose a consensus binding site for trans-acting factors—such as heterogeneous nuclear ribonucleoproteins (hnRNPs), polypyrimidine tract-binding protein 1 (PTB1), and nucleolinin—with translational regulatory properties. Another type of 3′ UTR regulatory sequence involves selenocysteine insertion sequence (SECIS) elements. These represent another stem-loop RNA structure found in mRNA transcripts that serve as protein-binding sites on UTR segments and direct the ribosome to translate the codon UGA as selenocysteines rather than as a stop codon. An example of this regulation can be found in selenoprotein P in plasma.

Another class of UTR binding site that affects the stability of mRNA is represented by the adenine- and uracil-rich (AU-rich) elements (AREs). AREs are lengths of mRNA consisting mostly of adenine and uracil nucleotides. These sequences destabilize mRNA transcripts through the action of riboendonucleases that stimulate poly(A) tail removal. Loss of the poly(A) tail is thought to promote mRNA degradation by facilitating attack by both the exosome complex and the decapping complex. Rapid mRNA degradation via AREs is a critical mechanism for preventing the overproduction of potent cytokines such as tumor necrosis factor (TNF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). AREs also

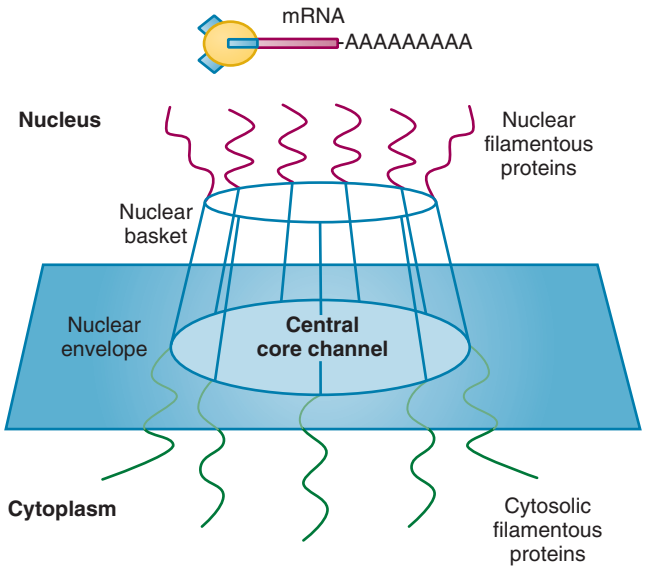

Figure 3-5 NUCLEAR EXPORT OF RNA THROUGH NUCLEAR PORE COMPLEXES. The central core of the nuclear pore complex consists of ring structure embedded in the nuclear envelope. Radiating in toward the nucleus is a nuclear basket that extends filamentous proteins in surveillance for mRNA. The central ring structure also radiates cytosolic protein filaments, which act to facilitate release of cargo into the cytoplasm.

regulate the synthesis of mRNA for proto-oncogenic transcription factors such as c-Jun and c-Fos. The AREs in these genes' mRNA target destruction of their mRNA transcripts in quiescent cells, preventing inappropriate cell proliferation that would occur if c-Jun and c-Fos were still active.

Eukaryotic mRNA messages are also subject to surveillance for accuracy by a mechanism termed *nonsense mediated decay (NMD)*. The NMD complex surveys the transcript for the presence of premature stop codons (nonsense codons) in the message. These premature stop codons can arise via either incomplete splicing mutations in DNA, transcription errors, or leaky scanning by the ribosome causing frame shifts. Detection of a premature stop codon by NMD triggers mRNA degradation by 5′ decapping, 3′ poly(A) tail removal, or endonucleolytic cleavage.

Translational efficiency can be regulated by cellular factors that bind mRNA in a sequence-specific manner. Iron metabolism is an excellent example of how cells coordinate uptake and sequestration of an essential metabolite in response to availability. Transferrin is a plasma protein that carries iron. Receptors for transferrin are expressed on cells requiring iron for maturation, such as erythroid progenitor cells. They mediate internalization of transferrin loaded with iron into the cytoplasm through receptor-mediated endocytosis. When a cell becomes iron deficient, a Krebs cycle enzyme, aconitase, is structurally altered, becoming an iron-responsive protein (IRP) so that it can bind to iron-responsive elements (IREs) in the UTR of transferrin receptor (TfR) mRNA (Fig. 3-6). UTR binding leads to stabilization of the TfR mRNA transcript and thus to greater availability for translation, which results in increased protein expression. However, when a cell has sufficient iron, aconitase is not altered, and TfR mRNA becomes unstable and prone to degradation. In that situation TfR receptor expression is low, and the fewer receptors import less iron.

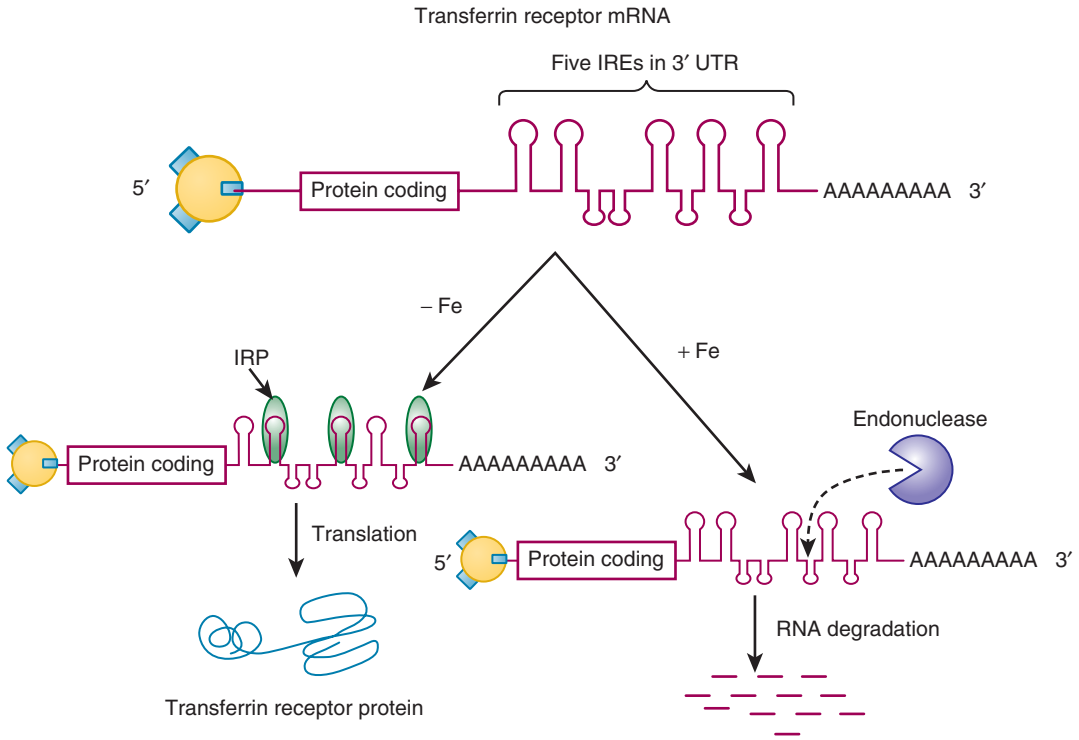

Figure 3-6 CONTROL OF TRANSFERRIN RECEPTOR GENE EXPRESSION. The transferrin receptor mRNA has five iron-responsive elements (IREs) in the 3′ end of its untranslated region (UTR). In an iron-deficient state (–Fe), iron-responsive proteins (IRPs) bind to IREs and stabilize the mRNA transcript for translation into protein product. In an iron-replete state (+Fe), IRPs are downregulated and the transferrin receptor mRNA is susceptible to endonucleases. Endonuclease cleavage of mRNA leads to RNA degradation and reduced availability of transcript for protein production.

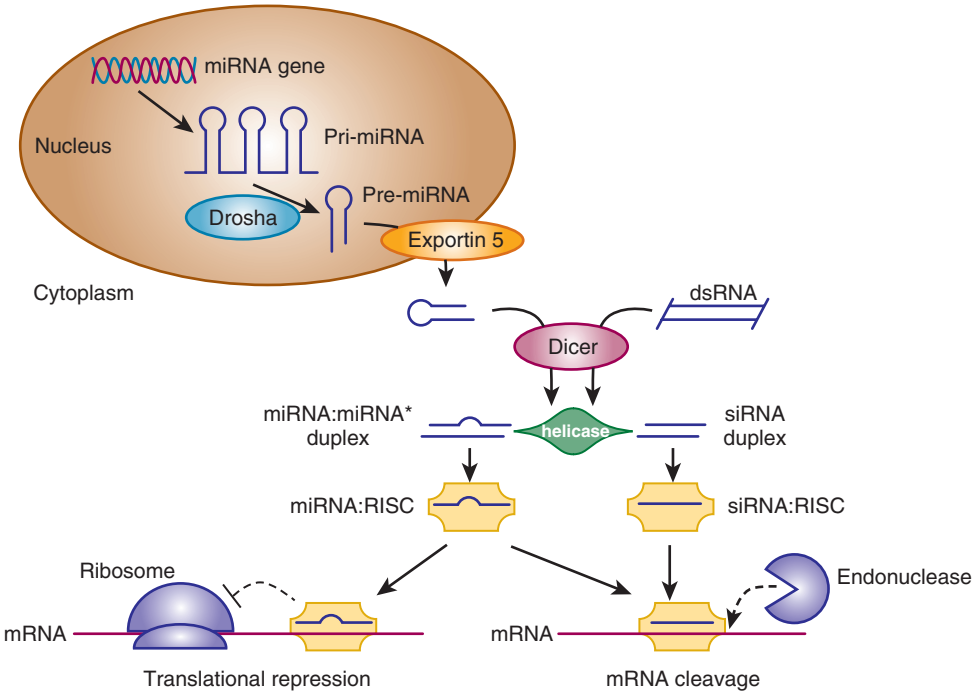

Figure 3-7 RNA INTERFERENCE AND CONTROL OF GENE EXPRESSION. The stem-loop of the primary miRNA (pri-miRNA) gene transcript is first cleaved through the action of the RNase III–related activity called Drosha, which takes place in the nucleus and generates the precursor miRNA (pre-miRNA). In the siRNA pathway the duplex RNAs are cleaved into 22 to 25 nucleotide pieces through the action of the enzyme Dicer in the cytosol. Processed miRNA stem-loop structures are transported from the nucleus to the cytosol via the activity of exportin 5. In the cytosol the processed miRNA stem-loop is targeted by Dicer, which removes the loop portion. The nomenclature of the mature miRNA duplex is miRNA:miRNA*, where the miRNA* strand is the nonfunctional half of the duplex. Ultimately, fully processed miRNAs and siRNAs are engaged by the RNA-induced silencing complex (RISC), which separates the two RNA strands. The active strand of RNA derived either from the miRNA or siRNA pathway is complementary or anti-sense to a region of the target mRNA. RNA interference results in blockade of translation by ribosomes and/or degradation of mRNA.

MICRO-RNA

Another powerful mechanism of regulating of gene expression at the RNA level involves small RNA molecules, termed *micro-RNA (miRNA),* bind to complementary (i.e., anti-sense) sequences on target mRNA transcripts. This binding results in either degradation or inhibition of translation and consequent silencing of gene expression. There are roughly 1000 miRNA molecules coded in the human genome, indicating how robust this regulatory mechanism is. miRNA usually contain 18 to 25 nucleotides, and each miRNA has the potential to target about 500 genes. Conversely, an estimated 60% of all mRNAs have one or more sequences that are predicted to interact with miRNAs. This biology, termed *RNA interference (RNAi)*, has also been exploited in the laboratory, where investigators design small interfering RNA (siRNA) to specifically repress expression of target genes to study artificially induced phenotypes. In these studies siRNAs are synthetically created to bind to complementary sequences within specific mRNAs. siRNAs are then transfected into cells, where they mediate destruction of their target mRNA through endogenous ribonucleases. Repression of gene expression in this manner has become known as "gene knockdown," a phrase widely used to describe the function of genes by assessing what function the cell lacks in the absence of the target gene's expression.

Naturally occurring miRNAs are produced from transcripts that form stem-loop structures, whereas laboratory-created siRNAs are produced from long, double-stranded RNA (dsRNA) precursors (Fig. 3-7). Similarly, both miRNAs and siRNAs are processed in the nucleus by a multiprotein complex called the RNA-induced silencing complex (RISC), which contains the ribonuclease III (RNase III) enzyme Dicer, DGCR8, and Argonaute. The specificity of miRNA and siRNA interactions with their target mRNAs mediates how they regulate gene expression. For example, the specificity of miRNA targeting is ruled by Watson-Crick complementarities between positions 2 to 8 from the 5′ end of the miRNA, with the 3′ UTR of their target mRNAs.

Two models have been proposed to explain how miRNAs and siRNAs interfere with the expression of target genes. The mechanisms involve both directed degradation and interference with translation of the target mRNA. In the case of directed mRNA degradation, the proposed model involves miRNA-mRNA binding and recruitment of RISC, which ultimately leads to degradation of the target mRNA. In the interference model it is believed that the interaction of miRNA, RISC, and mRNA blocks the ribosomal machinery along the mRNA transcript, preventing translation, yet sparing the mRNA from degradation. This latter model was hypothesized based on work with the *Caenorhabditis elegans* gene lin-14. In this example the amount of lin-14 mRNA does not decrease, but the protein product of the lin-14 mRNA is reduced. In the degradation model, the paired miRNA-mRNA becomes a target for double-stranded ribonucleases, which are thought to be part of the innate immune system as a defense against dsRNA viruses, such as rotavirus.

Various disease states have aberrant expression of miRNA. One example in chronic lymphocytic leukemia (CLL) is the *miR-15a/miR-16-1* cluster (located on chromosome 13q). When this cluster is deleted in B lymphocytes, there are higher levels of antiapoptotic proteins such as BCL2 and MCL1, but also higher levels of the tumor suppressor protein 53 (TP53). High levels of antiapoptosis yet with an intact TP53 tumor suppressor pathway could explain why 13q deletions in CLL are associated with an indolent form of the disease. Patterns of miRNA expression are correlated with disease progression in CML, although it is not clear whether these changes are causative

or epiphenomena. An example of the prognostic information that can be provided by changes in miRNA levels is *miR328,* whose expression levels fall significantly when CML begins to progress to blast crisis.

FUTURE DIRECTIONS

In summary, control of gene expression is a highly regulated process with several steps including the following: (1) DNA transcription into RNA, (2) splicing of mRNA into translatable transcripts, (3) modifying the mRNA transcripts for stability, (4) packaging the mRNA for export from the nucleus to the cytoplasm, and (5) regulation by miRNA. The ultimate goal of most posttranscriptional modifications is to make the mRNA available for translation into proteins. Perturbations in any of these steps can result in hematologic disease. Although the regulation of RNA has risk for disease at every step, it also possesses the promise of therapeutic intervention. RNA metabolism is a relatively underexplored pathway for diagnostic and therapeutic development in hematology, but that deficit is rapidly being overcome as more attention is being paid to analyzing for mutations of RNA metabolism in patients with hematologic diseases and targeting aberrant RNA pathways in an effort to restore normal gene expression.

CHAPTER 4

PROTEIN SYNTHESIS, PROCESSING, AND TRAFFICKING

Randal J. Kaufman and Laura Popolo

The final step in the transfer of the genetic information stored in deoxyribonucleic acid (DNA) into proteins is the translation of the intermediary messenger molecules, mRNAs (see Chapter 3). Protein synthesis occurs in the cytoplasm and generates a great variety of products endowed with a wide spectrum of functions. The complete set of proteins produced by a cell is called a *proteome* and is responsible for the remarkable diversity in cell specialization that is typical of metazoan organisms. In order to be functional, proteins need to be properly folded, assembled, and transported to the final destination if required. The cell has in its interior several membrane-bound compartments, termed *organelles,* such as the mitochondria, the peroxisomes, the nucleus, and the endoplasmic reticulum, to which the proteins may be targeted. Since each compartment serves a particular purpose, protein transport is crucial to maintain the identity and functions of each organelle. The intracellular physiology depends on the proper functioning of the organelles. In many cases, protein folding and processing are coupled with protein trafficking so that the targeting process is unidirectional and irreversible.

This chapter briefly describes how proteins are synthesized and then focuses on their processing and delivery to their appropriate destinations within the cell. An understanding of the machines that catalyze protein folding, assembly, and targeting is relevant to the study of hematology, providing a basis for an explanation of how malfunctions in these processes can cause blood disorders.

PROTEIN SYNTHESIS

Among the biosynthesis of macromolecules occurring in a cell, protein synthesis is the most important in quantitative terms. It is a highly energy-consuming process and proceeds through a mechanism that has been conserved during evolution. Proteins are synthesized by the joining of amino acids, each of which has characteristic physical-chemical properties (see Table 4-1 for single-letter designations). Peptide bonds are created by the condensation of the carboxyl group (COOH) of one amino acid with the amino group (NH_2) of the next. The free NH_2 and COOH groups of the terminal amino acids define the amino- or N-terminal end and the carboxyl- or C-terminal end of the resulting polypeptide chain. In many cases, multiple polypeptide chains assemble into a functional protein. For example, hemoglobin is formed by four polypeptide chains, two α-globin chains and two β-globin chains that assemble with heme, an iron-containing prosthetic group, to yield the functional protein designed to deliver molecular oxygen to all cells and tissues.

The whole process of protein synthesis is orchestrated by a large ribonucleoprotein complex, called the *ribosome.* The ribosome 80S (S stands for Svedberg unit and refers to the rate of sedimentation) is typical of mammalian cells and is constituted by a large subunit of 60S and a small one of 40S. Additional components are mRNAs, tRNAs, amino acids, soluble factors, ATP, and GTP. Preliminarily to protein synthesis is the activation of amino acids and their coupling to the cognate tRNAs. This crucial function is carried out by the aminoacyl-tRNA synthetases, which generate aminoacyl-tRNAs at the expenses of ATP and operate a quality control on the coupling reaction. Eukaryotic mRNA molecules typically contain a 5′-untranslated region (5′-UTR), a protein coding sequence that begins with the start codon AUG and ends with one of three stop codons (UAA, UAG, UGA), and a 3′-untranslated segment (3′UTR). The 5′ end carries a 7-methylguanosine forming a structure called a "cap" (m^7GpppN mRNA), whereas the 3′ end is polyadenylated. These modifications are required to protect the mRNA from degradation, for export out of the nucleus and for efficient recruitment of ribosomes for translation. Once in the cytoplasm, the 40S ribosomal subunit binds to the cap and then scans the mRNA toward the 3′ end until the translation start codon is encountered, usually the first AUG (underlined) located in a nucleotide context optimal for translation initiation called the Kozak sequence (A/GNNAUGG). The assembly of the 60S subunit with the 40S produces an 80S ribosome. A special tRNA specific for methionine, called the initiator ($tRNA_i^{Met}$) is required for the initiation of protein synthesis at the start codon. Aminoacyl-tRNAs ferry amino acids to the ribosome being joined together in sequence as the ribosome moves toward the 3′ end of the mRNA. The codons in the mRNA interact by base-pairing with the anticodon of the tRNAs so that amino acids are incorporated into the nascent polypeptide chain in the right order. Translation is terminated on encounter of a stop codon where the polypeptide is released. Typically, multiple ribosomes are engaged in the translation of a single mRNA molecule in a complex termed a *polyribosome* or *polysome*.

Protein synthesis is divided into three phases: initiation, elongation, and termination. Each phase requires soluble proteins (or factors) that transiently associate with the ribosomes and are called initiation, elongation, and termination (or release) factors; these factors are in turn termed *eIFs*, *eEFs*, and *eRFs*, respectively, where the prefix *e* indicates their eukaryotic origin. Many soluble factors required for protein synthesis belong to the G protein (guanine nucleotide-binding proteins) superfamily, which comprehends regulatory molecules of important cellular processes such as hormone or growth factors signaling pathways, membrane trafficking, or neurotransmission. Dysfunctions of G proteins are involved in human diseases such as cancer.

REGULATION OF mRNA TRANSLATION

There are two major general regulatory steps in mRNA translation that are mediated by the initiation factors eIF2 and eIF4. All cells regulate the rate of protein synthesis through reversible covalent modification of eIF2, a soluble factor required for the binding and recruitment of the Met-$tRNA_i^{Met}$ to the 40S ribosomal subunit.

eIF2 is a heterotrimeric G protein that can exist in an inactive form bound to GDP or an active form bound to GTP. The eIF2-GTP/Met-$tRNA_i^{Met}$ ternary complex binds to the 40S subunit. Joining of the 60S subunit triggers hydrolysis of GTP to GDP and thus converts eIF2 to the inactive form whereas the opposite reaction is catalyzed by a guanine nucleotide exchange factor (GEF) called *eIF2B*. Phosphorylation regulates eIF2 function. In reticulocytes, which synthesize hemoglobin almost as a sole protein, heme starvation blocks the synthesis of α- and β-globins by activating a protein

kinase, called *hemin-regulated inhibitor (HRI),* that specifically phosphorylates the α-subunit of eIF2. The phosphorylated form of eIF2 binds more tightly than usual to eIF2B, so that eIF2B is sequestered and not available for the exchange reaction. Thus eIF2 molecules remain in the GDP-bound form and translation of globin mRNA comes to a halt. This mechanism of translational inhibition is of more general significance because eIF2 is a target of phosphorylation by additional protein kinases that cause translational arrest in response to different conditions of cell stress, such as amino acid starvation, glucose starvation, and viral infection. Overall, phosphorylation by different stress-activated protein kinases converges on eIF2, which is thus a central key element of the so-called integrated stress response.

A second major control point of general protein synthesis is mediated by the eIF4 complex, which binds the cap and uses an ATP-dependent RNA helicase (eIF4A) activity and its stimulatory subunit (eIF4B) to unwind structural elements in the 5′ end of mRNA to make it accessible for 40S ribosome subunit binding. The subunit that binds the cap, eIF4E, is the least abundant factor regulating translation in mammalian cells. Increased levels of eIF4E stimulate protein synthesis and can contribute to oncogenesis. The cap-binding activity of eIF4E is inhibited by eIF4E-binding protein (eIF4EBP), which is regulated by phosphorylation mediated by the protein kinases AKT (also named *PKB*) and TOR. Since phosphorylated eIF4BP cannot bind eIF4E, eIF4EBP phosphorylation stimulates translation initiation. Extracellular factors, such as insulin, activate signaling pathways that stimulate protein synthesis through this mechanism. Insulin also activates eIF2B exchange activity and in the long term also increases the cellular ribosome content.

The efficiency of translation can also be modulated by cellular factors that bind mRNA in a sequence-specific manner. An example of this mode of regulation is the control of iron metabolism in animal cells. Key players of this system are (1) the iron-responsive element (IRE), a hairpin structure that is formed in the untranslated regions of the mRNAs, and (2) iron regulatory proteins (IRPs) that bind IRE. In the transferrin receptor (Tfr) mRNA and ferritin mRNA, IREs are located in the 3′-UTR and 5′-UTR, respectively. In iron-starved cells, the binding of IRPs to IREs results in the stabilization of Tfr mRNA and inhibition of translation initiation of ferritin mRNA. Conversely, when iron is abundant IRPs have a lower affinity to IREs and as a result Tfr mRNA is degraded whereas ferritin mRNA translation is stimulated. In this manner, cells can coordinately regulate iron uptake and iron sequestration in response to the changes in iron availability.

PROTEIN FOLDING

As the polypeptide emerges from the ribosome, it must fold in order to become a mature functional protein. The conformation of a protein is dictated chiefly by the primary structure. Some proteins can spontaneously acquire their mature three-dimensional conformation as they are synthesized in the cell and can even fold in a test tube by a self-assembly process. However, most polypeptides require assistance by other proteins in order to fold. These proteins are *molecular chaperones* that either directly assist protein folding or act to prevent aberrant interactions, such as aggregation that can occur in a densely packed environment like that of the cytosol of eukaryotic cells (protein concentrations of 200 to 300 mg/mL). Most molecular chaperones are heat-shock proteins (Hsps) and, in particular, are members of the Hsp70 family. Chaperones bind to short-sequence protein motifs, in many cases containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), chaperones help the nascent polypeptide to find its native conformation, one aspect of which is hiding hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol. Some properly folded protein monomers are assembled with other proteins to form multi-subunit complexes. The population of chaperones that assist folding and assembly in the cytosol is distinct from those that operate within the endoplasmic reticulum (ER) or mitochondria.

PROTEIN DEGRADATION

Proteins can contain mutations that prevent them from folding properly. Such misfolded proteins are marked for destruction and then degraded. The breakdown of these molecules is achieved in two major phases. First, the molecules are tagged with a polypeptide called ubiquitin, which is 76 residues long and covalently linked to the substrate protein. Second, the tagged molecules are ferried to an ATP-dependent protease complex called the *26S proteasome*, a multisubunit molecular machinery specialized in protein destruction.

Since its first discovery in carrying out the disposal of damaged and misfolded proteins, protein ubiquitylation was found in association with an increasing number of specific regulatory events involving a selective degradation of key regulatory proteins. Thus ubiquitylation is responsible for regulating a wide array of cellular processes, including differentiation, tissue development, induction of inflammatory responses, antigen presentation, cell cycle progression, and programmed cell death, also called *apoptosis* (see Chapter 16 for a review of cell death). In addition, ubiquitylation of surface receptors is involved in endocytosis, whereas ubiquitylation of histones activates DNA repair.

SORTING FROM THE CYTOSOL INTO OTHER COMPARTMENTS

Most of the proteins synthesized on free polysomes remain in the cytosol as cytosolic or soluble proteins. These include enzymes involved in many metabolic and signal transduction pathways, proteins required for mRNA translation or assembly of cytoskeleton. Other proteins are imported from the cytosol into the organelles, including the nucleus, the mitochondrion, and the peroxisome (Fig. 4-1).

In general, there are two types of protein trafficking. In one type, the protein crosses a lipid bilayer. The polypeptide crosses the membrane in an unfolded state through an aqueous channel composed of proteins. In the second type, the protein does not traffic across a lipid bilayer and is exemplified by trafficking into the nucleus or from the ER to the Golgi compartment. In these cases, proteins and protein complexes are transported in their folded/assembled state.

The sorting events are governed by sorting signals (i.e., short linear sequences or three-dimensional patches of particular amino acids) and by their cognate receptors (see some examples in Table 4-1). The first sorting decision occurs after approximately 30 amino acids of the nascent polypeptide have been extruded from the ribosome. If the nascent polypeptide lacks a "signal sequence," most often found near the amino-terminal end, the translation of the polypeptide is completed in the cytosol. Then the protein can either stay in the cytosol or be posttranslationally incorporated into one of the indicated organelles (see Fig. 4-1). If the protein does contain an amino-terminal signal, sequence is imported cotranslationally into the ER from where it can be targeted to the other compartments of the secretory pathway (see Fig. 4-1).

Targeting of Nuclear Proteins

One of the distinctive features of the eukaryotic cells is that the genome is contained in an intracellular compartment called a *nucleus*. This organelle is bounded by a double membrane that forms the nuclear envelope (NE) (see Fig. 4-1). The outer nuclear membrane is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. About 3000 nuclear pore complexes (NPCs) perforate the NE in animal cells. Although NPCs allow unrestricted, bidirectional movement of molecules smaller than 40,000 daltons, traversal of NPCs by larger molecules is tightly regulated. NPCs are approximately 120 nm in external diameter and comprise approximately 50 different proteins (nucleoporins), arranged in a complex cylindrical structure with an octagonal symmetry. Nucleoporins constitute the scaffold of the NPC and are

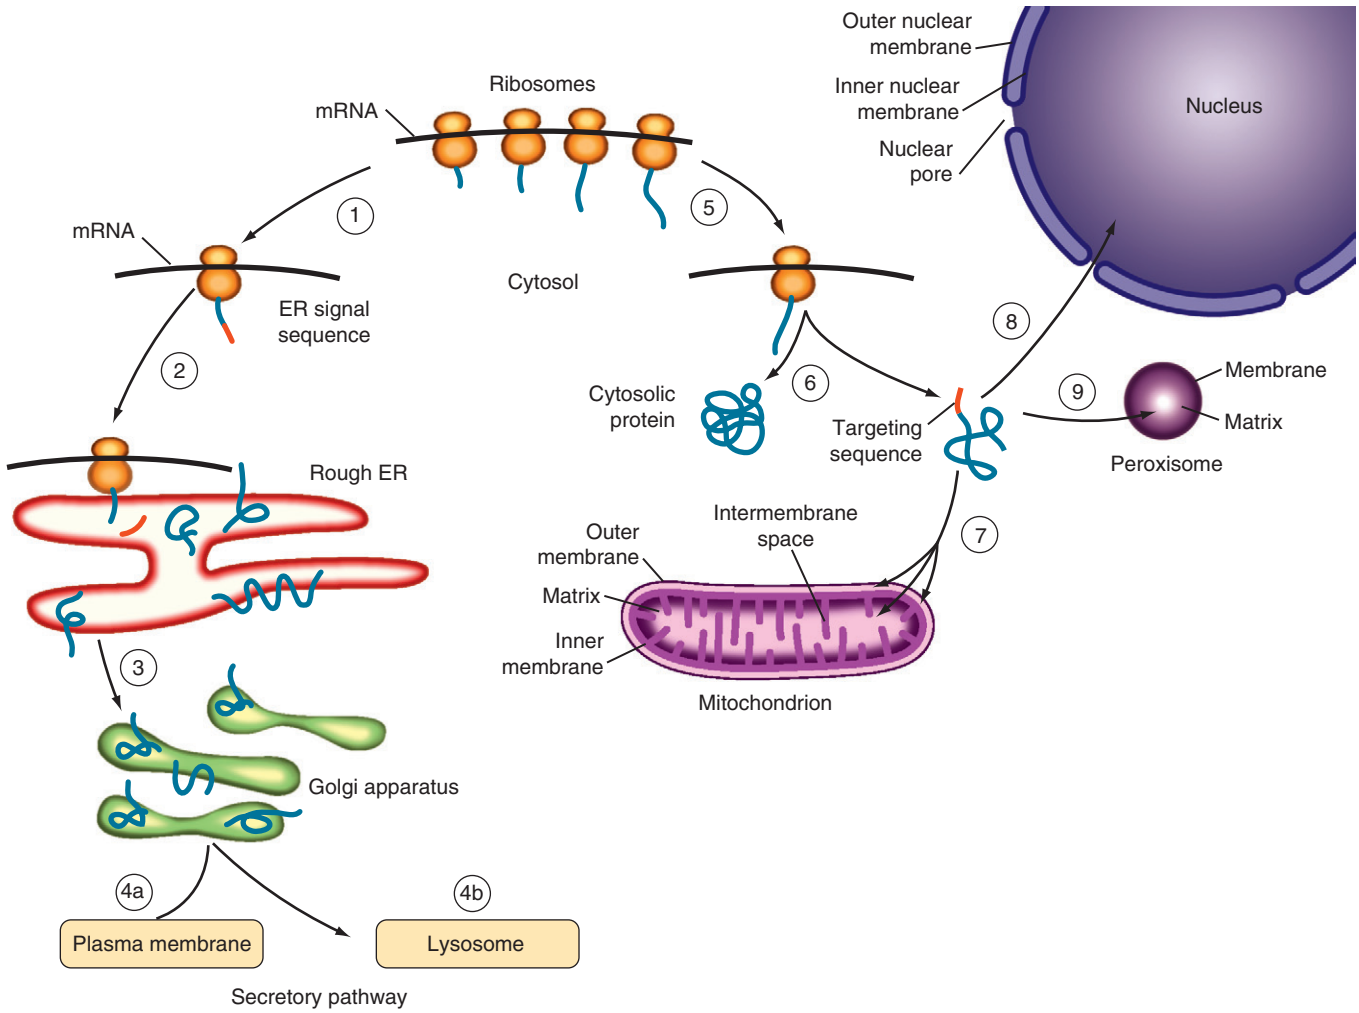

Figure 4-1 SORTING OF PROTEINS FROM THE CYTOSOL TO DIFFERENT DESTINATIONS. *Left,* Steps 1 to 4a and 4b: Sorting of proteins destined to organelles of the secretory pathway, ER, Golgi, plasma membrane, lysosome, or extracellular space. *Right,* Steps 5 and 6: Synthesis of a cytosolic protein. Steps 7, 8, and 9: Sorting of proteins to mitochondrion, nucleus, and peroxisome.

arranged in rings. In the inner ring, nucleoporins containing repeats of the hydrophobic amino acids phenylalanine and glycine (FG-repeats) seem to be essential for the movement of the cargo-carrier complexes and for creating a selectivity barrier against the diffusion of nonnuclear proteins. The FG-nucleoporin filaments protrude toward the inner core of the NPC, and the weak hydrophobic interactions between the FG-repeats and the cargo-carrier complexes mediate the passage of molecules.

NPCs are capable of importing and exporting molecules or complexes, provided that the molecules have an exposed nuclear localization signal (NLS) or nuclear export signal (NES). These signals are not always easy to predict. Some of the best-known signals are listed in Table 4-1. The function of these signals in importing or exporting a protein was analyzed by critically testing both the effects of amino acid substitutions on transport and the capability of the signal to target an attached reporter protein in or out of the nucleus. The nuclear localization signals are not cleaved off as occurs for other signals (see later discussion) and thus can function repetitively. Candidates exposing signals for nuclear import (e.g., transcription factors, coactivators or corepressors, DNA repair enzymes, ribosomal proteins, mRNA processing factors) or export (ribosomal subunits, mRNA-containing particles, tRNAs, etc.) are transported through the NPC in association with soluble carrier proteins, called *karyopherins* (also called *importins, exportins,* or *transportins*), which function as shuttling receptors of different protein cargos. According to the direction of transport, these carrier proteins are divided into two groups: (1) importins, if they bind their cargo on the cytoplasmic side of the NPC and release it on the other; and (2) exportins, if they bind their cargo in the nucleus and release it in the cytoplasm.

A small Ras-like GTPase, belonging to the G protein superfamily and called *Ran*, controls both the docking of carrier proteins with their cargo and the directionality of transport through cycles of GTP binding and hydrolysis. Fig. 4-2 exemplifies a cycle of import in the nucleus. An importin binds the cargo in the cytosol and then moves to the nucleus, where its association with Ran-GTP triggers the release of the cargo. The importin bound to Ran-GTP is transported back to the cytoplasm, where the conversion of GTP to GDP stimulated by a Ran-GAP protein (GTPase-activating protein) causes dissociation of Ran from the importin, which can initiate a new cycle. Ran-GDP is transported to the nucleus, where a Ran-GEF (guanine-nucleotide exchange factor) regenerates Ran-GTP. The movement from the nucleus to the cytoplasm occurs by formation of a Ran-GTP-exportin-cargo complex that is transported to the cytoplasm, where Ran-GAP triggers the hydrolysis of GTP. The conformational change of the exportin releases the cargo in the cytoplasm. The different localization of Ran-GEF and Ran-GAP and the continuous transport of Ran-GDP in the nucleus create an asymmetry that is important for the directionality of the process. In conclusion, karyopherins possess a cargo-binding domain but also binding domains for nucleoporins and Ran-GTPase.

The lack of NLS/NES removal during transport through the NPC enables multiple cycles of nuclear entry and exit, which is a particularly important mechanism for regulating the activity of proteins involved in DNA and RNA metabolism.

Table 4-1 Examples of Sorting Signals

Organelle	Signal Location*	Example
POSTTRANSLATIONAL UPTAKE		
Nucleus	Internal	SP**KKKRK***V**E* (import; NLS of SV40 large T antigen) **KR-**spacer **(**PAATKKAGQ**)-KKKK** (import; bipartite NLS of nucleoplasmin) LQLPPL***ER***LTL*D* (export; NES of HIV-1 rev)
Mitochondrion	N-terminal	MLGI**R**SSV**K**TCF**K**PMSLTS**KR**L (iron-sulfur protein of complex III)

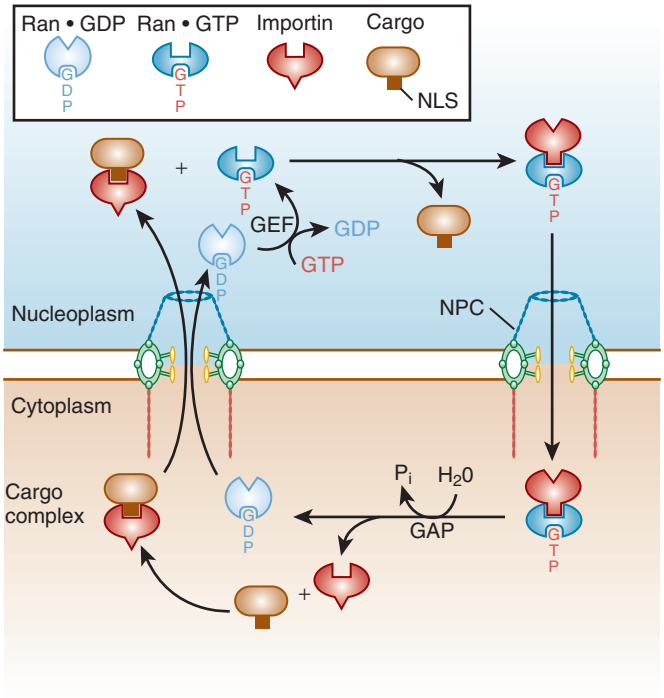

Figure 4-2 MECHANISM OF PROTEIN IMPORT INTO THE NUCLEUS. For description, see the text. *(Modified from Lodish H, Berk A, Matsudaira P, et al:* Molecular cell biology, *ed 5, New York, 2003, WH Freeman.)*

Of particular interest are some remarkable examples of the regulation of protein transport into the nucleus. For instance, NF-κB, a nuclear factor for the enhancer of the light κ chain in the B cells, is a key element of the stress response. This factor is normally retained in the cytoplasm by interaction with I-κB. The TNF-α–dependent phosphorylation of I-κB releases NF-κB, which exposes an NLS and migrates into the nucleus, where it activates transcription of several target genes. For the glucocorticoid receptor (GR), which is localized in the cytoplasm, the binding to the lipophilic ligand exposes an NLS, which is recognized by an importin and allows the translocation into the nucleus, where GR activates genes by binding to GR-responsive elements in their promoter.

Targeting of Mitochondrial Proteins

The mitochondrion is an essential cellular compartment in eukaryotes. Although it contains a genome organized in a circular DNA molecule and independent transcriptional/translational machinery, 98% of the approximately 1500 proteins that constitute mitochondrion proteome are encoded by nuclear DNA and are imported from the cytosol after their synthesis. A small number of highly hydrophobic proteins is encoded by mitochondrial DNA and is synthesized inside the organelle by a translational machinery of bacterial derivation using organelle-transcribed mRNAs.

Like nuclei, mitochondria have two membranes: the outer membrane (MOM) contacts the cytosol, whereas the inner one (MIM) forms numerous infoldings named *cristae,* in which reside the enzymes that synthesize ATP through reactions of the electron transport chain and oxidative phosphorylation. Whereas the MOM is permeable to small molecules (less than 5 kDa) and ions, the inner membrane is highly impermeable, a property essential to create an electrochemical gradient necessary to drive the synthesis of ATP. The space enclosed by the two membranes is the intermembrane space (IMS) and the space enclosed in the inner membrane is the *matrix.* The transport in the mitochondria seems to be unidirectional, and no known proteins are exported from these organelles. A remarkable exception is represented by apoptosis. Upon this condition, cytochrome c is released from the IMS to the cytosol, and this event triggers an intracellular pathway leading to death. Posttranslational translocation and sorting of nuclear-encoded proteins into the various mitochondrial subcompartments are achieved by the concerted action of translocases.

Precursor proteins usually have one of two targeting signals: (1) an amino-terminal presequence that is generally between 10 and 80 amino acid residues long and forms an amphipathic α-helix, which is rich in positively charged, hydrophobic, and hydroxylated amino acids (see Table 4-1); or (2) a less well-defined, hydrophobic targeting sequence distributed throughout the protein. The TOM (translocase of the outer membrane) complex functions as a single entry point into the mitochondria and is crucial for the biogenesis of the organelle and for the viability of eukaryotic cells. Preproteins translocate through it in an unfolded state in an N-to-C direction. TOM translocase is a heteromolecular protein complex whose central component is TOM40, an essential protein that forms the protein-conducting channel. After crossing the outer membrane, proteins segregate according to their signals and recognize two distinct translocases of the inner membrane, or TIMs (TIM23 and TIM22). Presequence-containing proteins are directed to the TIM23 complex, which mediates transport across the inner membrane, a process that requires the electrochemical membrane potential and the ATP-driven action of the matrix heat shock protein 70 (mtHsp70). Once in the matrix, the presequence is often cleaved by a mitochondrial processing peptidase. Proteins with internal targeting signals are guided to the TIM22 complex. Membrane insertion at the TIM22 is also dependent on the membrane potential.

In the context of cell biology, mitochondria play relevant roles in apoptosis, in the communication with the ER, and in oxidative stress. Among the proteins associated with the cytosolic side of MOM, those of the BCL2 family have both pro- and antiapoptotic functions. In addition, recent studies unveiled an ER-mitochondria linkage that is important in Ca^{++} homeostasis and phospholipids biogenesis, whereas oxidative stress generated in the mitochondria is connected to cell aging and senescence.

Targeting of Peroxisomal Proteins

Peroxisomes are membrane-bound compartments in which oxidative reactions that generate hydrogen peroxide, such as β-oxidation of fatty acids, occur. In this organelle, hydrogen peroxide is rapidly degraded by catalase to prevent oxidative reactions that have potential damaging effects on cellular structures. A single membrane surrounds the peroxisome, which encloses an interior matrix. This organelle lacks a genetic system and a transcriptional/translational machinery. Therefore all peroxisomal proteins are imported posttranslationally from the cytosol by proteins called *peroxins*.

The targeting of matrix proteins is directed by two types of peroxisomal targeting signals (PTSs). Type 1 (PTS1) is a carboxyl-terminal tri- or tetrapeptide, whereas type 2 (PTS2) is an amino-terminal peptide of nine amino acids (see Table 4-1). Two cytosolic peroxins, PEX5 and PEX7, recognize PTS1 and PTS2, respectively. These proteins function as cargo receptors. They bind cargo proteins in the cytosol, release them into the matrix, and cycle back to the cytosol. Other peroxins are involved in the import of membrane proteins. Although the mechanism of translocation is still elusive, soluble cargo proteins appear to cross the membrane in a folded state, or even as oligomers. At the peroxisomal membrane, the cargo-receptor complex associates with the docking complex, consisting of the peroxisomal membrane proteins PEX13 and PEX14. Ubiquitylation has been proposed to function in concert with ATPases associated to diverse activities (AAA^+ ATPases) to move proteins across the membrane using an ATP-dependent mechanism that resembles the retrotranslocation of misfolded proteins from ER lumen to the cytosol (see later discussion on ERAD).

One consequence of the existence of two different mechanisms for protein import is that when the import of matrix proteins is defective, membrane ghosts of peroxisomes persist in the cells. In contrast, when the import of membrane proteins is impaired, neither normal peroxisomes nor membrane ghosts are present. Defects in PEX3 underlie Zellweger syndrome, which is characterized by the presence of empty peroxisomes and abnormalities of the brain, liver, and kidney that cause death shortly after birth.

COTRANSLATIONAL PROTEIN TRANSLOCATION IN THE ENDOPLASMIC RETICULUM

The ER is an extensive membranous network that is continuous with the outer nuclear membrane and is responsible for the synthesis of the massive amounts of lipid and protein used to build the membranes of most cellular organelles. The ER comprises three interconnected domains: rough ER, smooth ER, and ER exit sites. The rough ER is so called because it is studded with bound ribosomes that are actively synthesizing proteins. Cells specialized in protein secretion, such as cells of the exocrine glands and plasma cells, are rich in rough ER. Smooth ER lacks ribosomes, is not very abundant in most cells (except hepatocytes), and is thought to be the site of lipid biosynthesis and of cytochrome P450-mediated detoxification reactions. Finally, ER exit sites are specialized areas of the ER membrane where transport cargo is packaged into transport vesicles en route to the Golgi apparatus.

Nascent secretory proteins are marked for import in the ER by the presence of an amino-terminal signal sequence (see Table 4-1). This sequence has a length of about 15 to 30 amino acids and displays no conservation of amino acid sequence, although it contains a hydrophobic core flanked by polar residues that preferentially have short side chains in proximity to the cleavage site. As the signal sequence emerges from the ribosome, it is recognized by the signal recognition particle (SRP), a ribonucleoprotein, and this binding induces a temporary arrest in translational elongation (Fig. 4-3). The docking of ribosomes to the ER occurs by interaction of the SRP with the SRP receptor. Upon binding of GTP to both the SRP and its receptor, the ribosome and the nascent chain are transferred to the Sec61 complex, allowing translation to resume. Preproteins translocate through the Sec61 complex in an N-to-C direction. As the nascent polypeptide emerges from the luminal side of the translocon, its signal sequence is cleaved by a signal peptidase.

In the absence of specific targeting sequences, proteins that completely translocate into the ER lumen traffic through bulk flow to the cell surface. In contrast, proteins that have specific targeting signals may be localized to the lumen of the ER, the Golgi compartment,

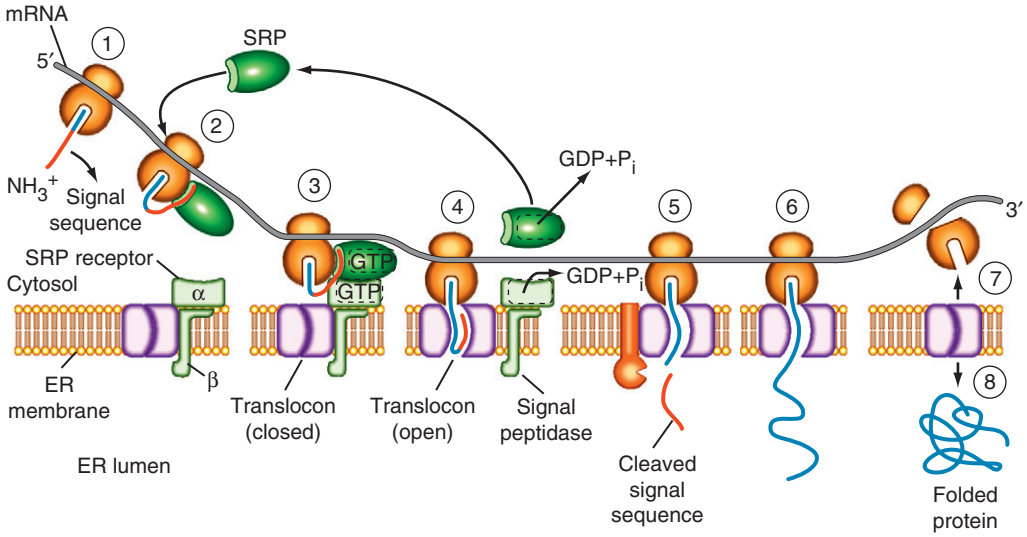

Figure 4-3 SYNTHESIS OF PROTEINS SORTED FOR IMPORT IN THE ER. The figure depicts the main steps of the cotranslational translocation of a secretory protein in the ER. *Steps 1 and 2:* The signal sequence of the emerging polypeptide is recognized by the SRP and binding induces a translation arrest. *Steps 3 and 4:* The binding of the SRP-nascent polypeptide-ribosome complex to the SRP-receptor triggers GTP hydrolysis of both SRP and SRP-receptor. The translocon channel (Sec61) opens and translation resumes. SRP is recycled. *Step 5:* The polypeptide chain elongates and emerges on the luminal side of the ER, where a signal peptidase removes the signal sequence. *Steps 6, 7, and 8:* The synthesis of the polypeptide proceeds until the end of translation and the protein assumes its native conformation (concurrent glycosylation is not shown). Ribosome dissociates and the single subunits are released.

or lysosomes. Other proteins that reside in membranes of the cell contain topologic sequences called *transmembrane (TM) domains* that consist of ≈20 largely apolar amino acids. When a transmembrane domain enters the translocon, the polypeptide is released laterally from the Sec61 channel into the lipid bilayer. Membrane proteins can assume different topologies according to the number and type of TM domains.

PROTEIN TRAFFICKING WITHIN THE SECRETORY PATHWAY

Proteins that enter the ER are transported toward the plasma membrane through a route that is called the *secretory pathway* (Fig. 4-4). Specific signals cause resident proteins to be retained in the ER, Golgi, or plasma membrane. Proteins may also be targeted from the Golgi compartment to lysosomes or from the plasma membrane to endosomes (see Fig. 4-4, pathways 8 and 9). Initially, the study of this complex protein trafficking took advantage of the use of yeast genetics to isolate temperature-sensitive mutants *(sec)*, which were defective at different stages of the secretory pathway. The subsequent characterization of *SEC* genes, thanks to the advent of DNA recombinant techniques, made possible the isolation of the counterparts in mammalian cells and the beginning of molecular and biochemical investigation of secretion. Many genes encoding products involved in secretion were found to be strikingly conserved from yeast to mammals, indicating the importance of this pathway for the life of a eukaryotic cell.

Transport through the secretory pathway is mediated by vesicles. Different sets of structural and regulatory proteins control the fusion of the appropriate vesicles with the target membrane. Sorting motifs dictate the selective incorporation of cargo proteins into those vesicles and their delivery to the intended destination. A major question in cell biology today is how the identity of the compartments of the secretory pathway is maintained while allowing unimpeded transit of other nonresident proteins.

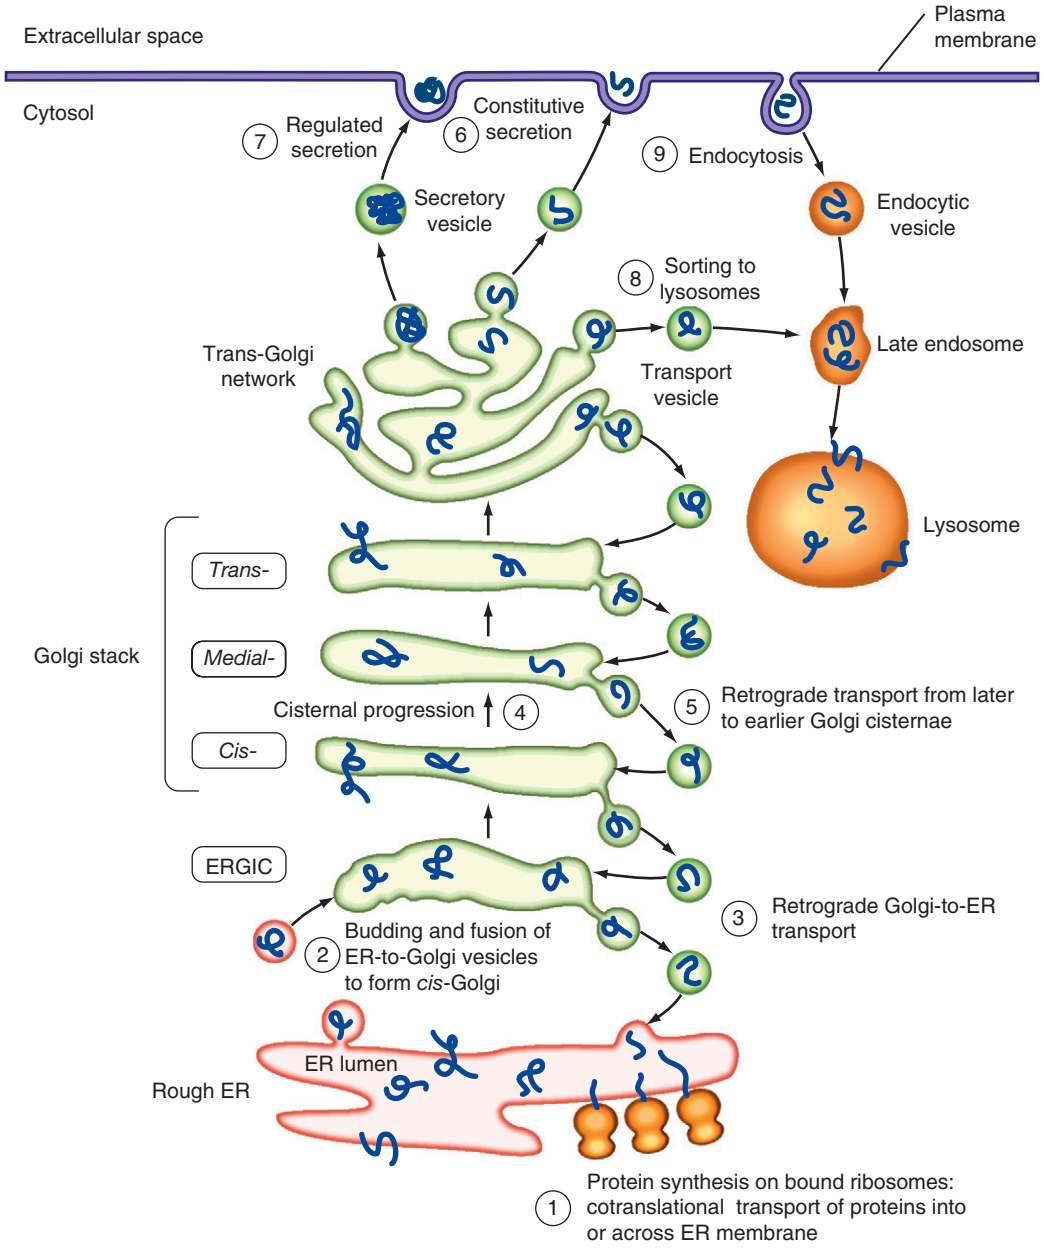

Figure 4-4 PROTEIN TRAFFICKING THROUGH THE SECRETORY PATHWAY. For details, see the text.

Processing of Proteins in the Endoplasmic Reticulum

Protein Folding in the Lumen of the ER

Protein chaperones facilitate protein folding in the ER, but amino acid posttranslational modifications such as asparagine(N)-linked glycosylation and disulfide bond formation are also involved. Proteins start to fold cotranslationally by interaction with a host of chaperones, among which is the Hsp70 family member BiP. In addition, there are folding catalysts that increase the rate of protein folding. For example, the proper pairing and formation of disulfide bonds is catalyzed by oxidoreductases, such as protein disulfide isomerase (PDI), which also shuffles nonnative disulfide bonds. In the current model the oxidation of two thiols produces a disulfide bond (S-S) in the substrate protein and concomitantly reduces two thiols of PDI, which return to the oxidized state by another thiol-disulfide exchange catalyzed by ERO1, a membrane-associated oxidoreductase. ERO1, a flavoprotein that was first discovered in yeast, returns to the oxidized state by transfer of electrons to molecular oxygen via its cofactor FAD. In contrast to the highly reducing environment of the cytosol, where disulfide bonds do not typically form, the lumen of the ER is very oxidizing so that disulfide bonds formation is favored.

Protein Modifications in the ER

Most proteins that enter the secretory pathway are modified by N-glycosylation (Fig. 4-5). This process starts with the transfer of a core oligosaccharide from a lipid-linked donor to an asparagine residue within the consensus sequence N-X-S/T of a nascent polypeptide (X can be any amino acid except proline). The N-linked oligosaccharide is composed of a glucose$_3$-mannose$_9$-N-acetylglucosamine$_2$ unit ($Glc_3Man_9GlcNac_2$). Further processing of the terminal sugars occurs in the ER and after the polypeptide transits the Golgi compartment (see Fig. 4-5).

Many blood proteins (e.g., immunoglobulins, antiproteases, coagulation factors) and many membrane proteins of the cell are glycosylated. Although glycan chains are often not required for the enzymatic activity of glycoproteins, they are important for the physical properties they confer and for many physiologic functions. Glycans protect proteins from protease digestion and heat denaturation, confer hydrophilicity and adhesive properties to the proteins, and mediate interaction with other proteins or receptors. A remarkable example is the hormone erythropoietin that requires a particular complex type of N-glycan chains for its biologic function to stimulate erythropoiesis.

In the recent years, several studies have revealed the importance of protein N-glycosylation in promoting folding. The addition of glycan chains may prevent aggregation or provide steric influences that affect polypeptide folding and disulphide bond formation and also mediate interaction with specific chaperones. In mammalian cells, N-linked oligosaccharides are also used as signal for monitoring protein folding. They are substrates for a complex chaperone system composed of the lectin chaperones calnexin (CNX) and calreticulin (CRT), Erp57 (an oxidoreductase), two glucosidases (GI and GII) and one folding sensor (UGT1) endowed with reglucosylation activity (UDP-glucose: glycoprotein glucosyltransferase). GI and GII remove the two terminal glucose residues to form a monoglucosylated N-linked chain (see Fig. 4-5) that is a ligand for CNX and CRT. Then another glucose residue is removed. UGT1 recognizes and reglucosylates N-linked oligosaccharides on proteins that have not completed the folding process. The addition of glucose residues allows reassociation with the CNX/CRT chaperone system for another attempt for the polypeptide to attain its proper conformation. Beside N-core glycosylation and oxidative folding, the ER is also the site of other kinds of protein modifications. A remarkable one is γ-carboxylation of glutamic acid residues. Although this is a

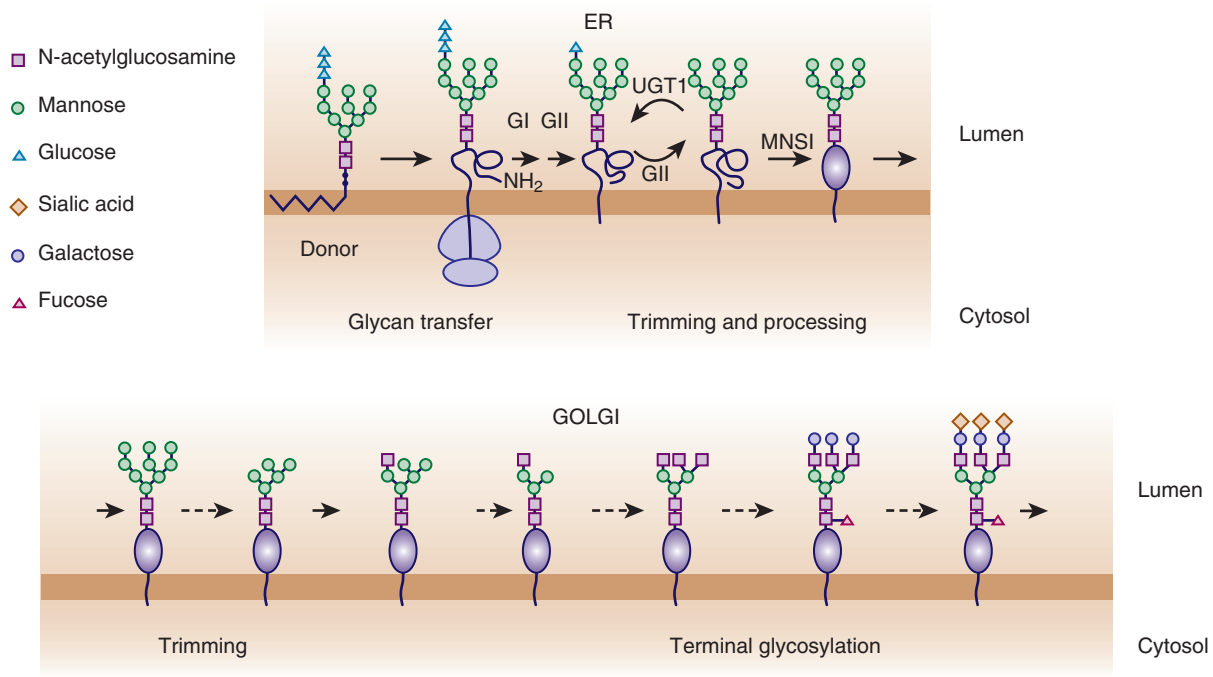

Figure 4-5 N-GLYCOSYLATION OF PROTEINS. In the lumen of the ER, a core oligosaccharide, $Glc_3Man_9GlcNac_2$, is transferred from a lipid-linked precursor (donor) to the asparagine residue of an N-X-S/T motif in a nascent polypeptide chain. The terminal glucoses are removed by GI and GII, and cycles of reglucosylation by UGT1 can occur *(curved arrows)*. When the protein is folded, one mannose is trimmed by ER-mannosidase I and the protein is transported to the Golgi. Core oligosaccharides are further trimmed by mannosidases to produce a $Man_5GlcNac_2$ unit. Further elaboration is catalyzed by glycosyltransferases that add various sugars and create branches. Bi-, tri-, and tetraantennary chains are generated. In the figure, only one pathway of terminal glycosylation is shown. *(Modified from Helenius A, Aebi M: Intracellular function of N-linked glycans.* Science *291:2364, 2001.)*

rather rare modification, it is crucial for the functionality of specific proteins and is essential for life (see box on Protein γ–Carboxylation: A Rare ER Posttranslational Modification Crucial for Life).

Destruction of Misfolded or Misassembled Proteins: ER-Associated Degradation

In the ER, proteins undergo a so-called quality control, which ensures that only correctly folded proteins exit the ER. Consequently, misfolded proteins are extracted from the ER folding environment for disposal. This mode of degradation is referred to as *endoplasmic reticulum-associated degradation* (ERAD). The destruction of proteins that undergo ERAD occurs in three major steps: (1) detection by the ER quality control machinery and targeting for ERAD, (2) transport across the ER membrane into the cytosol, and (3) ubiquitylation and release in the cytosol for degradation by the proteasome. One model for misfolded protein recognition is that hydrophobic patches or sugar moieties, which remain exposed on the protein for an extended period of time, are recognized by chaperone proteins such as PDI or by the CNX/CRT chaperone system. In a number of cases, retrotranslocation appears to require reduction of disulfide bridges by PDI. Similarly, BiP association with substrates (e.g., unassembled immunoglobulin light chains) can direct them to ERAD. If a protein remains in its unfolded state for an extended period of time, trimming of the $Man_8GlcNac_2$ also occurs. This processing is catalyzed by ER-degradation enhancer mannosidase α-like proteins EDEM1, EDEM2, EDEM3 (Htm1p in yeast). The current model postulates that the N-glycan structure generated by extensive de-mannosylation is the signal for glycoprotein degradation. ER-resident lectins (OS-9 and XTP3-B) bind to the remaining mannose residues and assist the retrotranslocation.

Proteins retrotranslocate to the cytosol through a protein-conducting channel, possibly formed by Derlin-1 and/or the complex. On their emergence at the cytosolic face of the ER membrane, substrates targeted for degradation start undergoing ubiquitylation. Tagged peptides are released into the cytosol in an ATP-dependent fashion, where they are degraded by the 26S proteasome. Fig. 4-6 illustrates the main steps of ERAD.

Protein γ–Carboxylation: A Rare ER Posttranslational Modification Crucial for Life

γ-Carboxylation of glutamic acid residues in the Gla domain serves to coordinate calcium ions and is essential for the proper biologic activity of factors involved in blood coagulation. These factors are prothrombin factors VII, IX, and X, which are involved in the coagulant response, and proteins C and S, which play roles in an antithrombotic pathway that limits coagulation. Other substrates of γ-carboxylase are less characterized, except for the bone proteins osteocalcin and matrix Gla protein, which both proved to require processing by γ-carboxylation for full activity.

This posttranslational modification is catalyzed by γ-glutamyl carboxylase, an ER membrane protein. Its obligate cofactor, reduced vitamin K, is produced by the action of vitamin K–epoxide reductase (VKOR), which converts oxidized vitamin K to the reduced form. The activity of VKOR is inhibited by warfarin, a potent anticoagulant compound. γ-Carboxylase homozygous null mutants manifested dramatic effects on development with partial midembryonic loss and postnatal hemorrhage. Similar effects were observed in prothrombin or factor V–deficient mice. Thus the results of these studies have suggested that the functionally critical substrates for γ-carboxylation are primarily restricted to components of the blood coagulation cascade. These results highlight the importance of a rare protein modification for blood coagulation.

The Unfolded Protein Response

The ER monitors the amount of unfolded protein in its lumen. When that number exceeds a certain threshold, ER sensors activate a signal transduction pathway. The set of responses activated by this pathway is called the unfolded protein response (UPR). A number of cellular insults disrupt protein folding and cause unfolded protein accumulation in the ER lumen. The UPR is an adaptive response signaled through three ER-localized transmembrane proteins: PERK, IRE1, and ATF6. These proteins function as sensors through the properties of their ER-lumenal domains and trigger a concerted response through the function of their cytosolic domains. The activation of the sensors result in a complex response aimed to (1) limit accumulation of unfolded protein through reducing protein synthesis, (2) increasing the degradation of unfolded protein, and (3) increasing the ER protein-folding capacity.

IRE1 is conserved in all eukaryotic cells and has protein kinase and endoribonuclease activities that, upon activation, mediate unconventional splicing of a 26-base intron from the XBP1 mRNA to produce a potent basic leucine zipper (bZIP) transcription factor. ATF6, upon accumulation of unfolded protein in the ER lumen, is transported to the Golgi compartment, where it is cleaved by two proteases, S1P and S2P. These enzymes release a cytosolic fragment of ATF6 containing a bZIP-transcription factor that migrates to the nucleus to activate gene transcription. S1P and S2P are two important Golgi proteases because they are also involved in the regulation of cholesterol metabolism. Finally, PERK-mediated phosphorylation of eIF2α attenuates general mRNA translation but, paradoxically, increases translation of the transcription factor ATF4 mRNA to also induce transcription of UPR genes. If the UPR adaptive response is not sufficient to correct the protein-folding defect, the cells enter apoptotic death. Activation of the UPR and defects in UPR are now known to be important factors that contribute to a wide range of disease processes, including metabolic disease, neurologic disease, infectious disease, and cancer.

Control of Exit From the Endoplasmic Reticulum

On achieving transport competence, proteins are granted access to higher-ordered membrane domains termed *ER exit sites*. At ER exit sites, membrane-bound and soluble proteins are concentrated into transport vesicles for trafficking to a network of smooth membranes called the *ER-Golgi intermediate compartment* (ERGIC, see Fig. 4-4). COPII complexes, composed of *co*at *p*roteins, concentrate and package the protein cargo into vesicles. COPII binds to cargo molecules either directly (if molecules span the membrane) or through intermediate cargo receptors and then provides some of the force that causes vesicle budding, thereby linking cargo acquisition to vesiculation (see box on The Genetic Basis of a Bleeding Disorder Revealed the First Receptor-Mediated Protein Transport System in the Early Secretory Pathway). Overall, the mechanisms involved in cargo recognition are poorly defined.

ER resident proteins are selectively sequestered in the ER both for the absence of export signals and to the presence of ER retention signals. Soluble luminal ER resident proteins are retained through a C-terminal ER tetrapeptide retention motif KDEL. Frequently, transmembrane proteins have either a C-terminal dilysine motif KKXX or an N-terminal diarginine motif XXRR, or variants thereof for transmembrane proteins. However, it is more accurate to indicate ER localization signals as "retrieval motifs" because proteins bearing these signals can transiently escape from the ER into the ERGIC, from which they are returned to the ER through the retrograde vesicular transport (see Fig. 4-4).

For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified, first in yeast and then in mammals. The KKXX motif has been shown to interact directly with the COPI coat protein complex that is involved in retrograde transport from the ER to the Golgi. Retrograde transport also serves to replenish the vesicle components lost as a result of anterograde (forward) transport. In

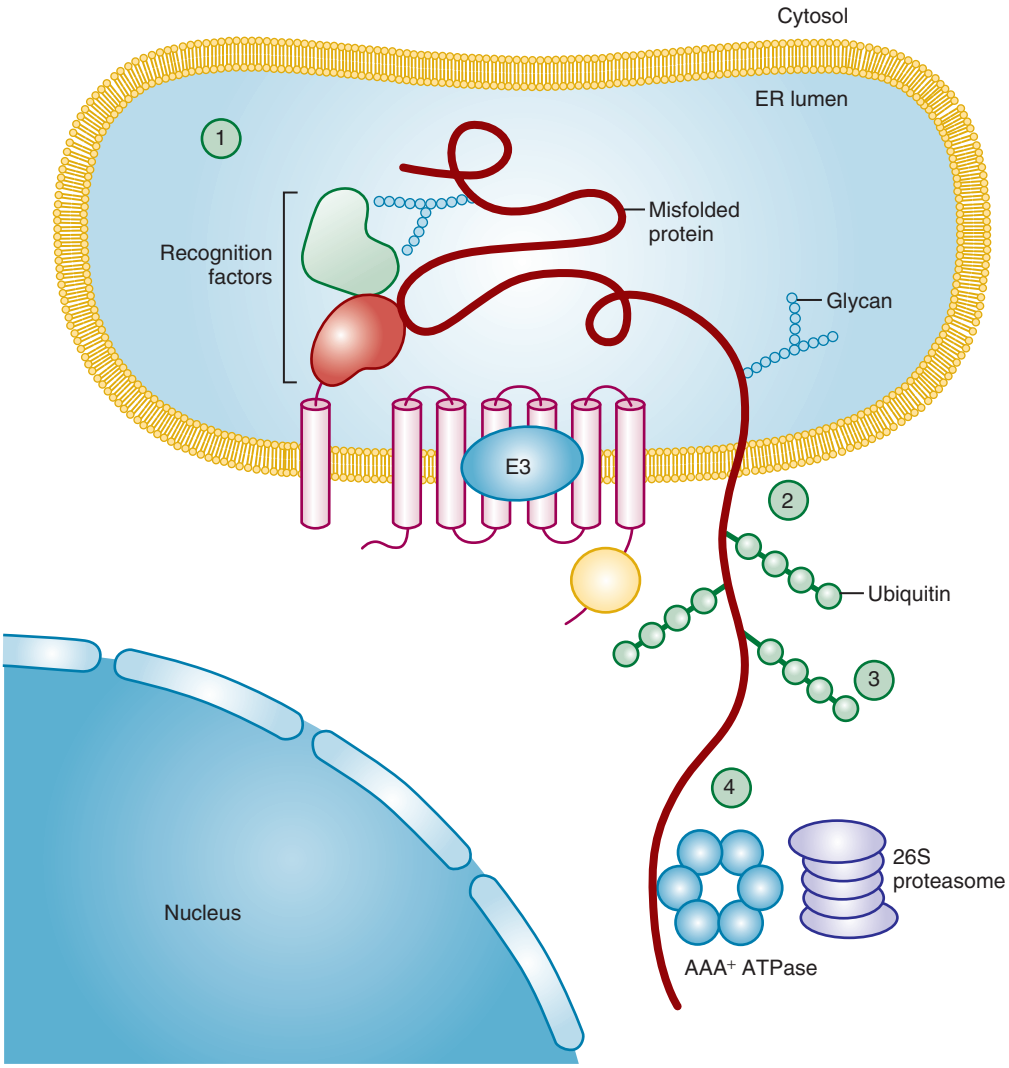

Figure 4-6 ER-ASSOCIATED PROTEIN DEGRADATION (ERAD). The figure depicts the steps in the degradation process of misfolded proteins in the ER. *Step 1:* Recognition factors (some of which are lectins), and ubiquitin ligases of the ER membrane cooperate in recognizing substrate proteins. *Step 2:* Proteins are exported into the cytosol via a so-far unidentified channel. *Step 3:* On the cytosolic face of the ER, the protein is ubiquitylated by an ER ligase. *Step 4:* The substrate is removed from the membrane by the AAA$^+$ ATPase Cdc48 and directed to the 26S proteasome. *(From Hirsch C, Gauss R, Horn SC, et al: The ubiquitylation machinery of the endoplasmic reticulum.* Nature *458:453, 2209.)*

The Genetic Basis of a Bleeding Disorder Revealed the First Receptor-Mediated Protein Transport System in the Early Secretory Pathway

In 2003 a form of bleeding disorder (hemophilia A) was found to be caused by defective secretion of coagulation factors V and VIII, two glycoproteins secreted into blood by specialized cells. Studies of human genetics combined with molecular biology led to the identification of two genes, *LMAN1* and *MCFD2*. LMAN1, or lectin mannose-binding protein1 (also referred to as ERGIC-53), is a transmembrane protein with a C-terminal cytoplasmic tail containing an ER-exit-motif (two phenylalanine residues, FF). This motif allows the interaction of LMAN1 with the COPII-coat proteins. The luminal domain of LMAN1 recognizes mannose residues and binds MCFD2 (multiple coagulation factor deficiency 2), a luminal protein, in a Ca^{++}-dependent manner. Both LMAN1 and MCFD2 are required in a complex for the recruitment of coagulation factors V and VIII into specific cargo vesicles. Of interest, loss of function mutations in either *LMAN1* or in *MCFD2* causes a bleeding disorder as a result of the combined deficiency of factors V and VIII. It has been shown that mutant forms of both LMAN1 and/or MCFD2 fail to recruit factor VIII into the vesicles. Thus the clotting factor deficiency is caused by a block in their export from the ER. Intriguingly, the LMAN1-MCFD2 complex appears to be required only for the secretion of factors V and VIII, as there are no significant reductions in any other plasma proteins. To date, the LMAN1-MCFD2 complex is the only well-defined cargo receptor in mammalian cells.

conclusion, selective protein exit from the ER is achieved by monitoring/regulating (l) transport competence of nascent proteins, (2) capture of cargo in transport vesicles, and (3) protein retention/retrieval for ER-localized proteins.

Intra-Golgi Transport and Protein Processing

Organization of the Golgi Apparatus

The Golgi complex is composed of a stack of flattened, membrane-bound cisternae that is highly dependent on microtubules for structural integrity. The stack of cisternae can be subdivided into three parts referred to as *cis, medial,* and *trans* with the cis and trans sides facing the ER and the plasma membrane, respectively (see Fig. 4-4). Both the cis and trans faces are associated with tubulovesicular bundles of membranes. The ERGIC comprises the bundle on the cis side of the Golgi stack and is the site where incoming proteins from the ER are sorted into those directed for anterograde or for retrograde transport. The tubulovesicular bundle at the trans side is called the *trans-Golgi network* (TGN; see Fig. 4-4).

A major feature of the Golgi is polarity. The processing events are temporally and spatially ordered because the processing enzymes have a characteristic distribution across the Golgi stack. In the Golgi, different types of modifications take place—for example, proteolytic processing, protein O-glycosylation, and elaboration of N-linked chains, phosphorylation of oligosaccharides, and sulfation of tyrosines.

Retention of Resident Golgi Proteins

Extensive analysis has failed to reveal a clear retention motif enabling subdomain-specific retention of resident Golgi proteins. Two possible models have been proposed. One model is retention by preferential interaction with membranes of optimal thickness. This is based on the finding that the transmembrane domains of Golgi proteins are shorter than transmembrane domains of plasma membrane proteins. These differences should allow a preferential interaction with the Golgi membrane lipid bilayer, which is thinner than that of plasma membrane. The other model is kin-recognition/oligomerization. This model postulates that proteins of a given subdomain of the Golgi membrane can aggregate into large detergent-insoluble oligomers as a way of minimizing lipid-protein contact. This would prevent the entry of proteins into the vesicles and thus their traffic to more distal cisternae. There is evidence in support of both models.

Protein Trafficking to and Through the Golgi Apparatus

Cargo proteins exit the ER in COPII-coated vesicles that enter the ERGIC and are ultimately delivered to the cis-Golgi either in vesicles or along extended tubules. However, the means whereby cargo proteins move across the Golgi complex from cis to trans remain controversial. Two models have been proposed. The vesicular transport model contends that anterograde transport occurs in vesicles or tubules and vesicles convey cargo in an anterograde direction. The second model suggests that there is a cisternal progression and maturation. This alternative model proposes that Golgi cisternae are not fixed structures but move forward from the cis side to the trans side, generating an anterograde movement. As cisternae mature, resident Golgi proteins that belong to more cis-like cisternae must be selectively pinched off in vesicles and trafficked back to the cis side of the Golgi stack. This would occur by COPI-mediated retrograde vesicular transport (see Fig. 4-4). Although which of these models is correct is currently unclear, most of the experimental data support the cisternal maturation model. In particular, technical progress in live-cell imaging provided evidence supporting a very dynamic nature of this organelle as expected by the progression/maturation model.

Sorting Events at the Trans-Golgi Network

Overview

The TGN is an important site of intracellular sorting, where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive pathway leading to the plasma membrane (see Fig. 4-4, pathways 6, 7, and 8). The secretion process is called *exocytosis*. The molecular basis for diversion of proteins into lysosomes and regulated secretory granules are described later.

Sorting Into Lysosomes

Lysosomes are acidic (pH of approximately 5.0 to 5.5), membrane-bound organelles containing numerous hydrolytic enzymes designed to degrade proteins, carbohydrates, and lipids. Soluble hydrolases are selectively marked for sorting into lysosomes by phosphorylation of their N-linked saccharides, which creates the mannose-6-phosphate (M6P) sorting signal. On arrival at the TGN, the modified hydrolase is bound by a cargo receptor, the M6P-receptor (M6P-R), which delivers it first to a "late endosomal compartment," where the low pH releases the hydrolase from the M6P-R. Subsequently, the hydrolase is delivered to the lysosome, and the M6P-R is recycled from the endosomes through retromer-coated vesicles to the TGN to be reused (for simplicity, the endosome to Golgi transport is not represented in Fig. 4-4).

The motif responsible for targeting M6P-R to lysosomes is YSKV and is recognized by all three distinct adaptor protein (AP) complexes (AP-l, -2, and -3) that contribute to delivery of cargo to lysosomes by linking cargo acquisition to vesiculation. Cargo recruitment occurs in a manner similar to that described for the COPI- and COPII-dependent vesicles, except that the cytosolic coat complex is clathrin. In addition to luminal hydrolases, lysosomes also contain a wide array of membrane proteins that are targeted to lysosomes via one of two consensus motifs: (1) YXXe, where X is any amino acid and e is any amino acid with a bulky hydrophobic side chain; and (2) a leucine-based motif (LL or LI). Trafficking of these membrane-bound proteins to lysosomes is indirect, proceeding first to late endosomes or the plasma membrane before their retrieval to lysosomes. Failure to accurately target lysosomal hydrolases underlies two well-known human diseases, Hurler syndrome and I-cell disease. Hurler syndrome is caused by a mutation in a hydrolase responsible for breakdown of glycosaminoglycans that prevents the hydrolase from acquiring the M6P modification, consequently preventing targeting to lysosomes. Similarly, in I-cell diseases undigested material accumulates in lysosomes because a mutation in the enzymes that create the M6P modification causes missorting of lysosomal hydrolases. Chapter 51 provides an overview of the lysosome storage diseases.

Autophagy: A Lysosomal Degradation Pathway

Autophagy, the most common name for *macroautophagy*, consists of the capture and degradation of cellular components and organelles. Cellular material is sequestered inside double-membrane vesicles, called *autophagosomes,* and degraded upon fusion with lysosomal compartments (Fig. 4-7). Raw precursors are then recycled for new biosyntheses. Constitutive autophagy serves to demolish damaged organelles or cytosolic components and contributes to the maintenance of cell homeostasis.

Autophagy is also stress responsive. It accelerates the catabolism of cellular components to sustain the demand of energy in adverse conditions and promotes cell survival. From yeast to human cells, starvation typically activates autophagy. Yeast has been a useful model microorganism to identify the first autophagy genes *(ATG)*, which

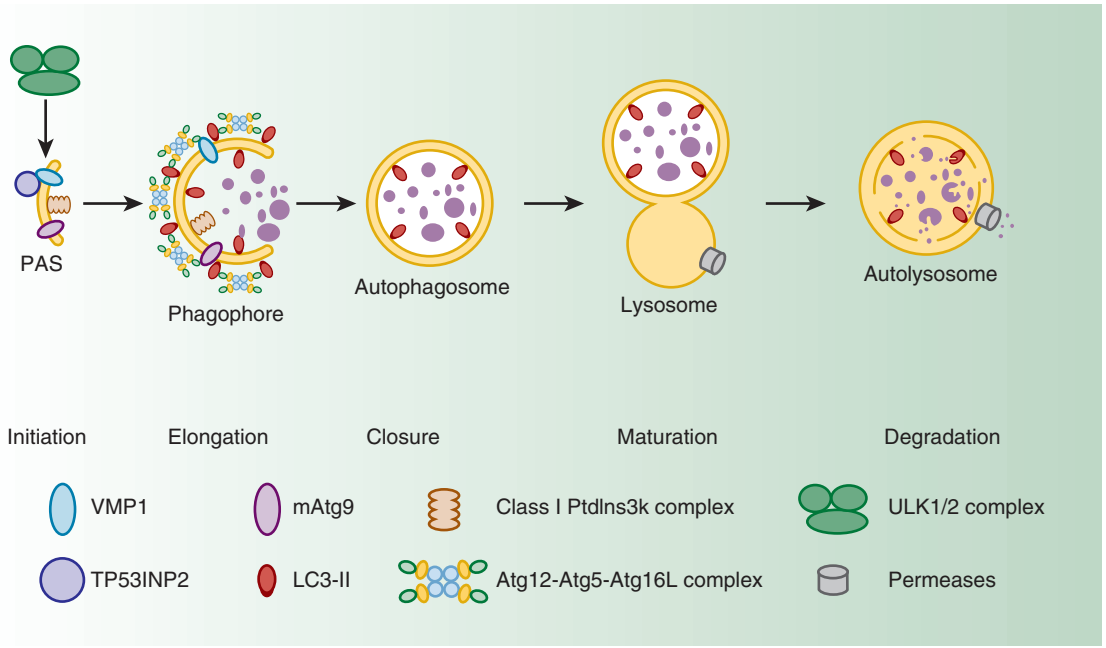

Figure 4-7 STEPS IN THE AUTOPHAGY PATHWAY. The scheme depicts different steps in mammalian autophagy. Shown on the left are the initiation at the PAS (phagophore assembly site); elongation and expansion of the phagophore; closure and completion of the autophagosome; autophagosome maturation via docking and fusion with an endosome and/or lysosome; breakdown and degradation of the autophagosome inner membrane and cargo; and recycling of the resulting molecules. In the lower part, some components of the molecular machinery are shown. The ULK complex is under the regulation of the protein kinase mTOR. *(Modified from Yang Z, Klionsky DJ: Mammalian autophagy: Core molecular machinery and signaling regulation.* Curr Opin Cell Biol *22:124, 2010.)*

allowed the subsequent isolation of the mammalian counterparts. ATG proteins are involved in the basic mechanism of autophagy, on which a complex regulation has been superimposed in mammals to respond to a wider variety of hormonal, environmental, and intracellular signals. An increasing body of evidence suggests that autophagy plays an important role in development and cell differentiation by facilitating cell and tissue remodeling. Remarkably, reticulocyte maturation in erythrocytes, which involves a mitochondria loss whose basis remained mysterious for decades, is partly dependent on autophagy (mitophagy).

Defects in constitutive autophagy compromise cell fitness. As a consequence, cells become more susceptible to tumorigenesis, neurodegenerative disorders, liver disease, aging, inflammatory diseases, and host defense against pathogens. However, recent evidence suggests that in established tumor cells, autophagy may represent an advantage for survival in hostile environments of the human body. Thus the autophagy may be regarded both as a target for tumor prevention or for cancer therapy.

Sorting Into Regulated Secretory Granules

In regulated secretion, proteins are condensed into stored secretory granules that are released to the plasma membrane after the cell has received an appropriate stimulus (see Fig. 4-4, pathway 7). After budding from TGN, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents from clathrin-coated vesicles. Mature secretory granules are thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis. One example of stimulus-induced exocytosis is the binding of a ligand to the T-cell antigen receptor (TCR) complex on a cytotoxic T lymphocyte. Conjugation of a cytotoxic T cell with its target causes its microtubules and associated secretory granules to reorient toward the target cell. Subsequently, the granules are delivered along microtubules until they fuse with the plasma membrane, releasing their contents for lysis of the target cell. Following release of the granule contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

Endocytic Traffic

Overview

Substances are imported from the cell exterior by a process termed *endocytosis* (see Fig. 4-4, pathway 9). Endocytosis also serves to recover the plasma membrane lipids and proteins that are lost by ongoing secretory activity. There are three types of endocytosis: (1) phagocytosis (cell eating), (2) pinocytosis (cell drinking), and (3) receptor-mediated endocytosis. Defects in endocytosis can underlie human diseases. For example, patients with familial hypercholesterolemia (FH) have elevated serum cholesterol because of mutations in the low-density lipoprotein (LDL) receptor that prevent the endocytic uptake of LDL and its catabolism in lysosomes.

Phagocytosis

During phagocytosis cells are able to ingest large particles (greater than 0.5 µm in diameter). Phagocytosis serves not only to engulf and destroy invading bacteria and fungi but also to clear cellular debris at wound sites and to dispose of aged erythrocytes. Primarily, specialized cells such as macrophages, neutrophils, and dendritic cells execute phagocytosis. Phagocytosis is triggered when specific receptors contact structural triggers on the particle, including bound antibodies, complement components as well as certain oligosaccharides. Then the polymerization of actin is stimulated, driving the extension of pseudopods, which surround the particle and engulf it in a vacuole called *phagosome*. The engulfed material is destroyed when the phagosome fuses with a lysosome, exposing the content to hydrolytic enzymes. In addition, phagocytosis is a means of "presenting" the pathogen's components to lymphocytes, thus eliciting an immune response.

Pinocytosis

Pinocytosis is the constitutive ingestion of fluid in small pinocytotic (endocytic) vesicles (0.2 μm in diameter) and occurs in all cells. Following invagination and budding, the vesicle becomes part of the endosome system, which is described in the following section. The plasma membrane portion that is ingested returns later through exocytosis. In some cells, pinocytosis can result in turnover of the entire plasma membrane in less than 1 hour.

Receptor-Mediated Endocytosis

This is a means to import macromolecules from the extracellular fluid. More than 20 different receptors are internalized through this pathway. Some receptors are internalized continuously whereas others remain on the surface until a ligand is bound. In either case, the receptors slide laterally into coated pits that are indented regions of the plasma membrane surrounded by clathrin and pinch off to form clathrin-coated vesicles. The immediate destination of these vesicles is the endosome.

The endosome is part of a complex network of interrelated membranous vesicles and tubules termed the *endolysosomal system.* The endolysosomal system comprises four types of membrane-bound structures: early endosomes (EEs), late endosomes (LEs), recycling vesicles, and lysosomes. It is still a matter of debate whether these structures represent independent stable compartments or whether one structure matures into the next. The interior of the endosomes is acidic (pH about 6). Endocytosed material is ultimately delivered to the lysosome, presumably by fusion with LE. Lysosomes are also used for digestion of obsolete parts of the cell in the process of autophagy (described in more detail earlier).

During the formation of clathrin-coated vesicles, clathrin molecules do not recognize cargo receptors directly but rather through the adaptor proteins, which form an inner coat. The AP-2 components bind both clathrin and sorting signals present in the cytoplasmic tails of cargo receptors close to the plasma membrane. These internalization motifs are YXXϕ (where ϕ is a hydrophobic amino acid), the most common motif, and the NPXY signal that was first identified in the LDL receptor. For receptors that are internalized in response to ligand binding, the internalization signal may also be generated by a conformational change induced by the binding of the ligand. Through the specificity of the AP-2 complex, the capture of a unique set of cargo receptors is linked to vesiculation, resulting in concentration of the cargo. The coated pit pinches off from the plasma membrane by the action of a GTP binding protein, dynamin, which forms a ring around the neck of each bud and contributes to the vesicle formation. After release and shedding of the clathrin coat, the vesicle fuses with the EE compartment.

SPECIFICITY OF VESICULAR TARGETING

As described earlier, COPI- and COPII-vesicles transport material early in the secretory pathway, whereas clathrin-coated vesicles transport material from the plasma membrane and Golgi. Coating proteins assemble at specific areas of the membrane in a process controlled by the coat-recruitment GTPases: ARF1 is responsible for the assembly of COPI coats and clathrin coats at Golgi membranes, whereas SAR1 is responsible for COPII coat assembly at the ER membrane. In yeast the process of vesiculation in the transport from the ER to Golgi has been dissected at a molecular level. On the cytosolic face of the ER membrane, Sar1p is activated by the ER-localized GEF Sec12p. Sar1-GTP assembles with the Sec23-Sec24 complex whose Sec24 subunit binds directly or through a membrane receptor to specific signals displayed by the cargo. This prebudding cargo complex recruits the outer layer Sec13-Sec31 complex leading to coat polymerization, membrane deformation, and COPII-vesicle formation. Mutations in gene encoding the human homolog of Sec24 or Sar1 are responsible for severe human diseases (see box on ER-to-Golgi Trafficking: Defects in Assembly of the COPII Coat Cause Severe Human Disorders).

ER-to-Golgi Trafficking: Defects in Assembly of the COPII Coat Cause Severe Human Disorders

Proteins processed in the ER are transported to the Golgi through vesicles that form and bud from the membrane upon assembly of the COPII coat on the cytosolic face of the ER. Mutations in single genes encoding COPII components result in two inherited human disorders. *SAR1B* mutant gene causes a fat malabsorption disease in which enterocytes fail to secrete large lipoprotein particles into the bloodstream. A single missense mutation in *SEC23A* is responsible for cranio-lenticulo-sutural dysplasia (CLSD), a syndrome characterized by facial dysmorphism, skeletal defects, late-closing fontanels, and sutural cataracts.

The severe phenotype of CLSD and lack of defects in other secretion-based processes, such as digestion or insulin signaling, is likely to be due to low expression in calvarial osteoblasts of the isoform *SEC23B* that cannot compensate for the lack of a functional SEC23A. The mutant F382L-*SEC23A* is incapable to support ER-derived vesicle formation both *in vitro* and *in vivo* since it impairs SEC13-SEC31 complex recruitment necessary for COP II coat polymerization. Consistently, skin fibroblasts from patients with CLSD exhibit distended ER cisternae from which tubular extensions protrude. Cargo protein receptors (ERGIC-53/LMNA1) and SAR1 protein enrich at the presumed ER exit sites of the tubular protrusions.

Clathrin-coat assembly at the plasma membrane is also thought to involve a GTPase, but its identity is unknown. These regulatory proteins also ensure that membrane traffic to and from an organelle are balanced.

After budding, vesicles are transported to their final destination by diffusion or motor-mediated transport along the cytoskeletal network (microtubules or actin). The molecular motors kinesin, dynein, and myosin have been implicated in this process. The vesicles undergo an uncoating process before fusion with the correct target membrane. Both transport vesicles and target membranes display surface markers that selectively recognize each other.

Three classes of proteins guide the selectivity of transport vesicle docking and fusion: (1) complementary sets of vesicle SNAREs (v-SNAREs; *SNARE* derived from SNAP receptor, or *soluble NSF association protein receptor*) and target membrane SNAREs (t-SNAREs), which are crucial for the fusion; (2) a class of GTPases, called *Rabs*; and (3) protein complexes called *tethers,* which, together with Rabs, facilitate the initial docking of the vesicles to the target membrane.

Although Rab GTPases function as the master regulators of membrane traffic, they are themselves regulated by factors that control their activation by GEFs or their inactivation by GAP, proteins that stimulate the intrinsic GTPase activity.

FUTURE DIRECTIONS

The mechanisms regulating protein synthesis, processing, degradation, and transport are under intense investigation. Protein motifs and their cognate receptors have been identified for many intracellular sorting and processing reactions. Studies are now directed to elucidate these processes at a molecular level by resolution of the three-dimensional structures of the proteins involved in protein processing and trafficking. The future challenge will be to find ways of exploiting this knowledge to intervene in the numerous disease states that result from errors in these processes.

CHAPTER 5

PROTEIN ARCHITECTURE: RELATIONSHIP OF FORM AND FUNCTION

Jia-huai Wang, Angela Toms, Ming-Ming Zhou, and Michael J. Eck

Previous chapters have outlined the central dogma of molecular biology: the storage of genetic information in DNA and its regulated transcription into messenger RNA and eventual translation into proteins. In this chapter, we briefly outline the chemical structure of proteins and their posttranslational modifications. We explain how the properties of the 20 amino acids of which proteins are composed allow these polymers to fold into compact, functional domains and how particular domains and motifs have been assembled, modified, and reused in the course of evolution. Finally, we describe a sampling of proteins and domains of relevance to the hematologist and explore briefly how point mutations, chromosomal translocations, and other genetic alterations may modify protein structure and function to cause disease.

AMINO ACIDS AND THE PEPTIDE BOND

Proteins are linear polymers of the 20 naturally occurring amino acids, linked together by the peptide bond. All of the amino acids share a common core or backbone structure and differ only in the side chain emanating from the central α-carbon of this core. The common backbone elements include an amino group, the central α-carbon, and a carboxylic acid group. Peptide bonds are formed by reaction of the carboxylic acid of one amino acid with the amino group of the next amino acid in the chain. This reaction is templated and catalyzed by the ribosome and leads to the release of water formed by the loss of an –OH group from the carboxylic acid of one amino acid residue and a hydrogen atom from the amino group of the next residue in the chain. Coupling of multiple amino acids together via the peptide bond produces the repeating main-chain structure of the polypeptide chain, composed of the amide (NH) nitrogen, alpha carbon (Cα), and carbonyl carbon (CO), followed by the amide nitrogen of the next amino acid in the chain (Fig. 5-1, *A*). The resonant, partial double-bond character of the peptide bond prevents rotation about this bond; thus the five main-chain carbon, nitrogen, and oxygen atoms of each peptide unit lie in a plane. The conformational flexibility in the polypeptide chain is conferred by rotation about the bonds on either side of the α-carbon atom; these bond angles are referred to as *phi* and *psi angles*. The angle of the N–Cα bond is known as the *phi angle* (Φ), and the angle of the Cα–CO bond is known as the *psi angle* (ψ).

The primary structure or primary sequence of a protein is the order in which various residues of the 20 amino acids are assembled into the polypeptide chain, and this sequence is critically important for determining the three-dimensional fold and thus function of the protein. It is the diverse chemical structure and physicochemical properties of the 20 amino acid side chains that guide the three-dimensional fold of proteins and also provide for the enormous repertoire of protein function—from catalysis of myriad chemical reactions to immune recognition to establishment of muscle and skeletal structure.

The amino acids can be divided into general classes based on the properties of their side chains and, in particular, their propensity to interact with water. Hydrophobic amino acids have aliphatic or aromatic side chains and include alanine, valine, leucine, isoleucine, proline, methionine, and phenylalanine. The hydrophobic amino acids predominate in the interior of proteins, where they are sequestered from water. They tend to pack against each other via van der Waals interactions, which contribute to the overall stability of folded protein domains. Charged amino acids include those with acidic side chains (aspartic acid and glutamic acid) and those with basic side chains (lysine, arginine, and histidine). Histidine merits special mention, because it is the only amino acid whose side chain can be protonated or unprotonated, and therefore charged or uncharged, in physiologic ranges of pH. For this reason, histidine is part of many enzyme-active sites. For example, in the serine proteases of the coagulation cascade, an active-site histidine acts as a general base, accepting and then releasing a proton in sequential steps of the enzymatic reaction. Polar amino acids include serine, threonine, tyrosine, asparagine, glutamine, cysteine, and tryptophan. Both polar and charged residues can form hydrogen bonds with each other, with the protein main chain, and with water or ligand molecules. Hydrogen bonds refer to the attractive interaction of a proton covalently bonded to one electronegative atom (usually a nitrogen or oxygen in proteins) with another electronegative atom. Hydrogen bonds are an important contributor to the stability of proteins and to the specificity of protein-protein and protein-ligand interactions. Some polar amino acids (e.g., threonine, lysine, tyrosine, and tryptophan) are amphipathic—that is, they have both polar and hydrophobic traits. This dual nature makes them well suited for participating in protein-protein interactions, where they may be alternately exposed to solvent or buried upon formation of a complex.

Protein Secondary Structure

The alternating pattern of hydrogen bond donating amide groups and hydrogen bond accepting carbonyl groups gives rise to repeating elements of protein structure that are stabilized by hydrogen bonds between these main-chain groups. These secondary structure elements include α-helices and β-sheets. In an α-helix, the main chain adopts a right-handed helical conformation in which the carbonyl oxygen of the i^{th} residue in the polypeptide chain accepts a hydrogen bond from the amide nitrogen of the $(i + 4)^{th}$ residue (see Fig. 5-1, *B*). The pattern may repeat for only a few residues, forming a single turn of α-helix, or for more than 100 residues, forming dozens of turns of helix. There are 3.6 residues per turn of helix, and the pitch or rise of the helix is 1.5 Å per residue or 5.4 Å per turn. The side chains of residues in an α-helix project outward, away from the central axis of the helix. Often a polar side chain will "cap" the end of a helix by forming a hydrogen bond with the otherwise unpartnered amide or carbonyl group at the N- or C-terminal end of the helix.

In β-sheet secondary structure, the protein backbone adopts an extended conformation and two or more strands are arranged side by side, with hydrogen bonds between the strands. The strands can run in the same direction (parallel β-sheet) or antiparallel to one another. Mixed sheets with both parallel and antiparallel strands are also possible (see Fig. 5-1, *C*). In β-sheets, the side chains of a given strand extend alternately above and below the plane defined by the hydrogen-bonded main chains. Other common types of secondary structure include a variant of the helix with an $i + 3$ hydrogen bonding pattern

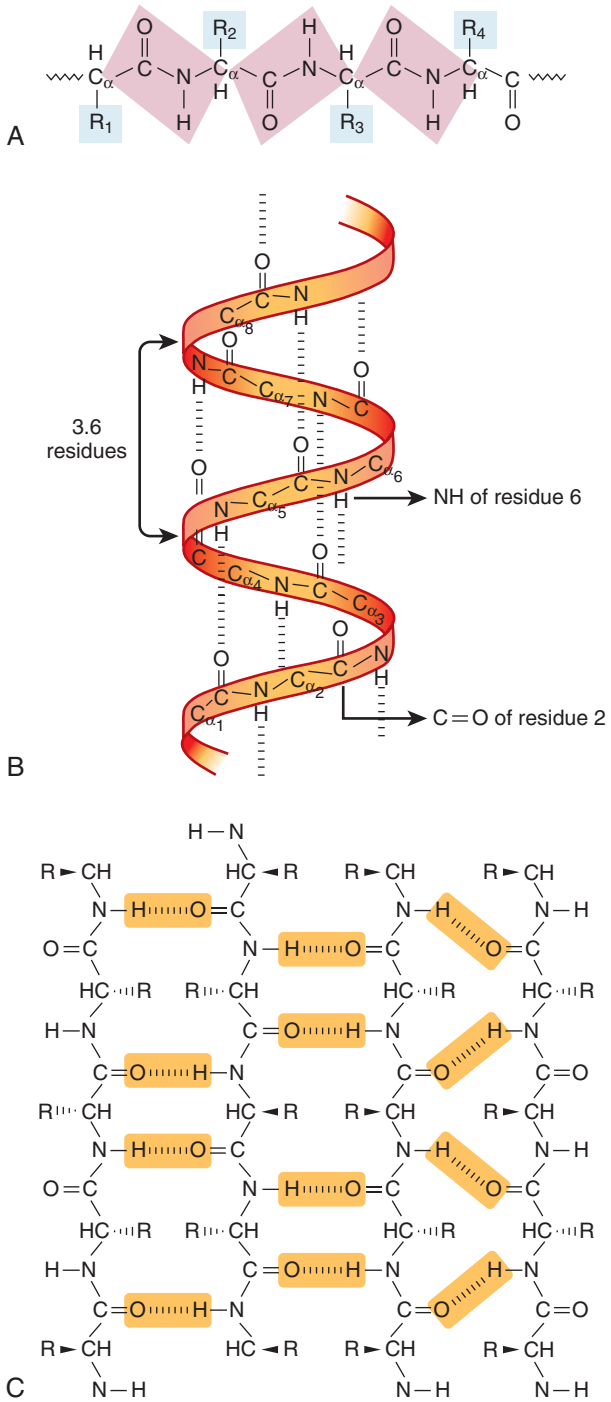

Figure 5-1 A, Diagram showing a polypeptide chain where the main-chain atoms are represented as peptide units, linked through the Cα atoms. Each peptide unit is a planar, rigid group *(shaded in pink)* and has two degrees of freedom; it can rotate around the Cα-CO bond and the N-Cα bond. The peptide bonds are depicted in the trans conformation; adjacent Cα carbons and their side chains *(highlighted in blue)* on opposite sides of the N- Cα bond. This is the preferred configuration for most amino acids, because it minimizes steric hindrance. **B,** The α-helix. The hydrogen bonds between residue *n* and residue *n* + 4, which stabilizes the helix, are shown as dashed lines. **C,** Schematic drawing of a mixed β-sheet. The first three β-strands are antiparallel to one another, whereas the last two β-strands are parallel. The hydrogen bonds that stabilize these structures are highlighted.

(the 3_{10} helix) and specific types of β-turns, short segments connecting other elements of secondary structure that are stabilized by β-sheet–like hydrogen bonds. Although any of the amino acids can be found within α-helices or β-sheets, the special characteristics of proline and glycine merit mention. The cyclic structure of proline means that it lacks an amide proton; thus it introduces an irregularity in hydrogen bonding, for example, leading to a "kink" in an α-helix. Glycine lacks a side chain—it has only a second hydrogen atom on its α-carbon—and therefore has less steric restriction and can adopt a wider range of backbone phi and psi angles. This added flexibility means that glycine tends to disfavor regular secondary structure.

Because proteins are large and complicated structures, they are typically illustrated with "ribbon" diagrams that trace the path of the polypeptide backbone. In such representations, helices are drawn as helical coils or cylinders, and β-strands appear as elongated rectangles with an arrow as a guide to the direction of the protein chain from its amino- to carboxy-terminal end. Specific side chains of amino acids of functional interest can then be added to illustrate a particular feature.

Disulfide Bonds and Posttranslational Modifications

The covalent structure of proteins is commonly modified in structurally and functionally important ways beyond the linear coupling of amino acids via the peptide bond. Regulated proteolysis can be considered a posttranslational modification and can serve an important regulatory role, as in the cleavage of prothrombin in the blood-clotting cascade. The structure of cell-surface and extracellular proteins is often stabilized by disulfide bonds, which are covalent bonds formed between the thiol groups of juxtaposed cysteine residues. In general, disulfide bonds are not found in intracellular proteins, where the reducing environment disfavors their formation. Disulfide bonds can form between cysteines within the same polypeptide chain, stabilizing the fold of the polypeptide backbone, or they may covalently join two different polypeptide chains, for example, the heavy and light chains of immunoglobulins. In addition to their role in disulfide bond formation, cysteine residues often contribute to protein stability via their participation in metal ion coordination, in particular zinc, which is often bound by conserved sets of cysteine and histidine residues in small protein domains.

A number of functional groups are appended to proteins to regulate their function, localization, protein interactions, and degradation. Examples of these posttranslational modifications (PTMs) include phosphorylation, glycosylation, ubiquitylation, methylation, acetylation, and lipidation. PTMs occur at distinct amino acid side chains or peptide linkages and are most often mediated by enzymatic activity and can occur at any step in the "life cycle" of a protein. As discussed later, a number of protein domains have evolved to recognize and bind specifically to proteins labeled by a particular PTM. Protein phosphorylation on serine, threonine, or tyrosine residues is one of the most important and well-studied posttranslational modifications. Phosphorylation is mediated by protein kinases and can activate or deactivate many enzymes through conformational changes and thus plays a critical role in the regulation of many cellular processes, including cell cycle, growth, apoptosis, and signal transduction pathways. Protein glycosylation encompasses a diverse selection of sugar-moiety additions to proteins that ranges from simple monosaccharide modifications to highly complex branched polysaccharides. Glycosylation has significant effects on protein folding, conformation, distribution, stability, and activity. Carbohydrates in the form of asparagine-linked (N-linked) or serine/threonine–linked (O-linked) oligosaccharides are major structural components of many cell-surface and secreted proteins. Protein methylation on arginine or lysine residues is carried out by methyltransferases with S-adenosyl methionine (SAM) as the primary methyl group donor.[1] Methylation is an important mechanism of epigenetic regulation—histone methylation and demethylation influence the availability of DNA for transcription. N-acetylation, the transfer of an acetyl group to the amine nitrogen at the N-terminus of the polypeptide chain, occurs in a majority of eukaryotic proteins.

Lysine acetylation and deacetylation is an important regulatory mechanism in a number of proteins. It is best characterized in histones, where histone acetyltransferases (HATs) and histone deacetylases (HDACs) regulate gene expression via modification of histone tails. Many cytoplasmic proteins are also acetylated, and therefore acetylation seems to play a greater role in cell biology than simply transcriptional regulation.[2] Lipidation is a modification that targets proteins to membranes in organelles, vesicles, and the plasma membrane. Examples of lipidation include myristoylation, palmitoylation, and prenylation. Each type of modification gives proteins distinct membrane affinities, although all types of lipidation increase the hydrophobicity of a protein and thus its affinity for membranes. In N-myristoylation, the myristoyl group (14-carbon saturated fatty acid) is transferred to a N-terminal glycine by N-myristoyltransferase. The myristoyl group does not always permanently anchor the protein in the membrane; in a number of proteins the N-terminal myristoyl group has been observed to pack into the protein core. N-myristoylation can therefore act as a conformational localization switch, in which protein conformational changes influence the availability of the handle for membrane attachment.

The Domain Structure of Proteins

In general, the minimal biologically functional unit of three-dimensional protein structure is the protein domain. Domains are locally compact and semi-independent units of usually contiguous polypeptide chain. The common size of a domain is between 100 and 200 amino acid residues, although much larger and smaller domains are also frequently observed. Protein domains are composed of closely packed secondary structure elements—α-helices, β-sheets, or a combination of both—and the loops that connect them. Domains are stabilized by hydrophobic interactions among these elements and typically have very hydrophobic central cores, with more hydrophilic amino acids extending from their surface. Alternating patterns of hydrophobic residues in secondary structure elements are a reflection of the role of hydrophobicity in driving protein folding and stability. Helices are often amphipathic, and they pack in a folded domain in such a way that their hydrophobic face is buried in the domain interior and their hydrophilic face is exposed on the surface. Likewise, β-sheets often have a buried hydrophobic face and an exposed hydrophilic face. The importance of the hydrophobic core to the stability of protein domains is highlighted by the fact that point mutations that introduce polar or charged residues into a protein interior often cause misfolding and thus a loss of function. Although these general characteristics are shared by protein domains that are found in an aqueous environment, such as that on the cytosol or on the cell surface, membrane-embedded proteins have very different properties, reflective of their residence in the lipid bilayer. Several common domain structures representing different categories with regard to their secondary structure composition are shown in Fig. 5-2.

Deciphering this basic protein building block is key for understanding the structure and evolution of proteins. Kinetically, the domain structure of a protein may simplify the folding process into

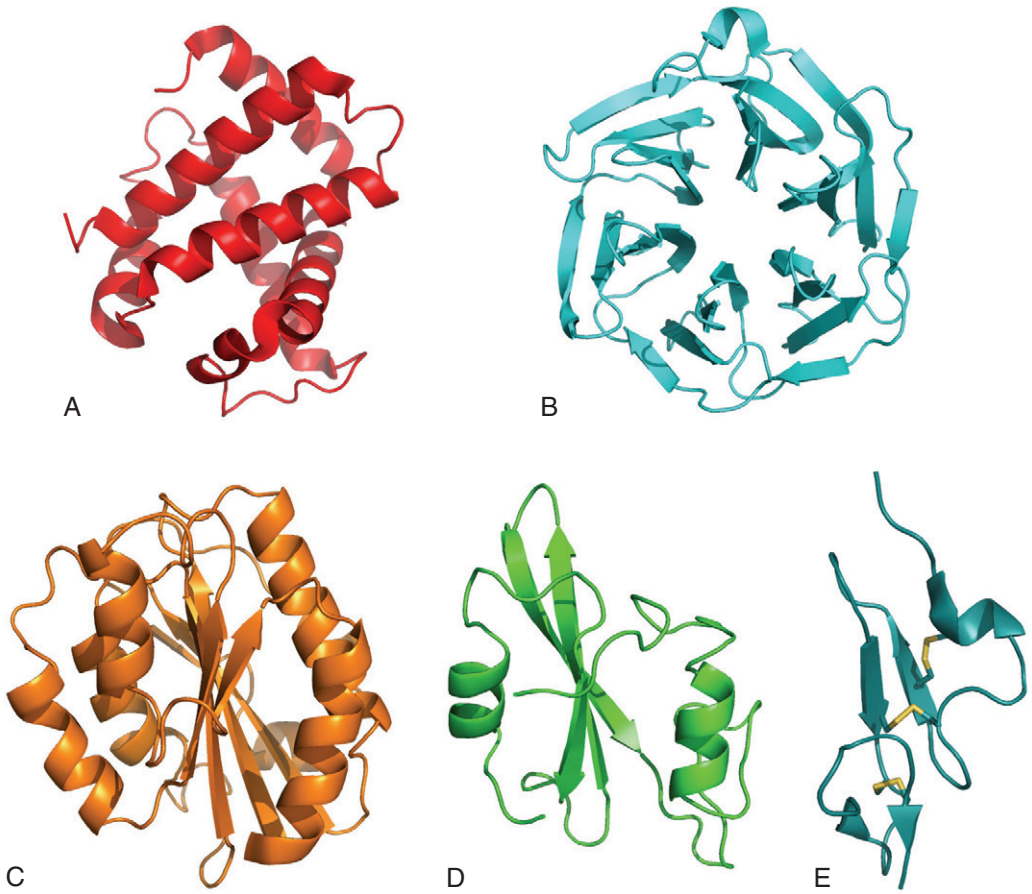

Figure 5-2 SEVERAL COMMON DOMAIN STRUCTURES. **A,** The α-globin domain of hemoglobin, made up by all α-helices (PDB entry 2MHB). **B,** The β-propeller domain, composed of all β-strands, existed in many extracellular matrix and cell surface proteins (PDB entry 1NPE). **C,** The I domain, comprising alternate β-strand and α-helix, from integrin (PDB entry 1ID0). **D,** SH2 (Src homologue 2) domain, consisting of sequentially separate β-strands and α-helices, typically found in tyrosine kinases (PDB entry 1FMK). **E,** The EGF (epidermal growth factor) domain, mainly maintained by 3-4 disulfide bonds, found in many extracellular matrix proteins and cell adhesion molecules (PDB entry 1UZJ).

a stepwise course.[3] Thus a long amino acid sequence may fold into multiple domains rapidly and correctly. For many proteins, individual domains fold in a cotranslational manner; from the N-terminal region, a growing nascent polypeptide chain immediately begins to fold domain-by-domain during translation from the ribosome in a very efficient manner.[4] Genetically, it was long suspected that the exon structure of genes was correlated with the domains structure of proteins.[5] Recent multigenome analysis does find a strong correlation between domain organization and exon-intron arrangement in genomic DNA. The exon-domain correlation facilitates extensive exon shuffling events during evolution,[6] although it is not necessarily always one-exon/one-domain. This mechanism ensures that a stable and functionally efficient domain can be repeatedly used as a module assembled into many proteins with shared functions. A well-known early example is the nucleotide-binding domain identified in various dehydrogenases; its robust alternate β-strand–α-helix–β-strand fold provides a common structural unit for these enzymes.[7]

Recent computational approaches demonstrate that almost all of a growing number of known sequences come from new combinations of individual protein domains, and as a consequence more than 70% of all sequences can be partially modeled from known structures with homologous domains.[8] This has been reflected in the human genome sequence.[9] Impressive progress has already been made in computational protein prediction and design, principally based on the known structural elements.[10]

Many proteins are composed of multiple domains, which may confer multiple functions, couple a targeting function to a catalytic function, or provide for allosteric regulation. The following sections will highlight the structure of a few proteins and domains that are of central and recurring importance in hematology in order to illustrate the relationship between domain architecture and function. Representative examples have been chosen from the extracellular space (the immunoglobulin domain), intracellular signaling (protein kinase domain), and nuclear gene regulation (transcription factors and domains involved in epigenetic regulation).

The Immunoglobulin Domain and Variations

As implied by its name, the immunoglobulin (Ig) domain was first recognized in antibodies.[11] A detailed discussion on antibody biology can be found in Chapter 22. The human genome project has identified the Ig superfamily (IgSF) as the largest superfamily in the human genome, owing to its extensive usage in more recently developed immune system in vertebrates.[9] In fact, the Ig domain is an evolutionarily ancient structural unit that can be found in *Caenorhabditis elegans*.[12] Although Ig-like domains also exist in a few intracellular proteins, they are found predominately in the extracellular space and are the most abundant structural unit found in cell surface receptors, serving key recognition functions in both the immune and nervous systems. Along with a handful of other modular domains such as fibronectin type III domains and EGF domains, they form modular structures of most receptor molecules on the cell surface.[13]

An Ig domain is composed of roughly 100 residues, folding into two β-sheets packing face-to-face, forming a β-barrel. This distinctively folded structure is commonly known as the Ig fold. Since an antibody consists of a variable domain and one (in light chain) or three (in heavy chain) constant domains, Ig domains have correspondingly been classified into V-set and C-set. A V-set Ig domain has β-strands A, B, E, and D on one sheet and A′, G, F, C, C′, and C″ strands on the other (Fig. 5-3, *A*), whereas a C-set Ig domain lacks A′, C′, and C″ strands on either edges (see Fig. 5-3, *B*). The two sheets are linked together by a conserved disulfide bond between B strand and F strand (reviewed in Williams et al[14]). The V-set Ig domains of heavy chain and light chain combine to make up the antigen-binding site, where hypovariable sequences cluster into three CDR (complementarity-determining region) loops that connect β-strands (see Fig. 5-3, *A*). Fig. 5-4, *A*, depicts how a broadly neutralizing antibody 2F5's CDR loops form an antigen-binding pocket, grabbing the antigenic peptide from the HIV surface protein.[15] In the figure, only the antibody's two variable domains are shown. A similar structural platform is used in cellular immunity by T-cell receptors (TCR), which, distinct from antibodies, recognize an antigenic peptide along with the MHC (major histocompatibility complex) molecule that presents the peptide on the infected cell surface. In this case, CDR3 loops of TCR's variable domains play a key role in antigen recognition, whereas germline-encoded CDR1 and CDR2 loops are responsible for contacting the polymorphic region of the MHC molecule, with CDR1 also taking part in peptide binding.[16,17] Fig. 5-4, *B*, illustrates a typical structure of a TCR in complex with an antigenic peptide bound to the MHC molecule. An extensive discussion on the role of these proteins in cellular immunity can be found in Chapter 19.

A number of variations on the Ig fold are found in other cell surface receptors. These Ig-like domains include the topologically similar fibronectin type III domains[18] and the domains of cadherins, which also assumes the same strand topology.[19] The fibronectin domains and cadherins lack the disulfide bridge found in the Ig domain, which demonstrates the thermodynamic robustness of the immunoglobulin fold.

Further variations are found in modular cell surface receptors, which often have a V-set Ig-like domain as their most N-terminal

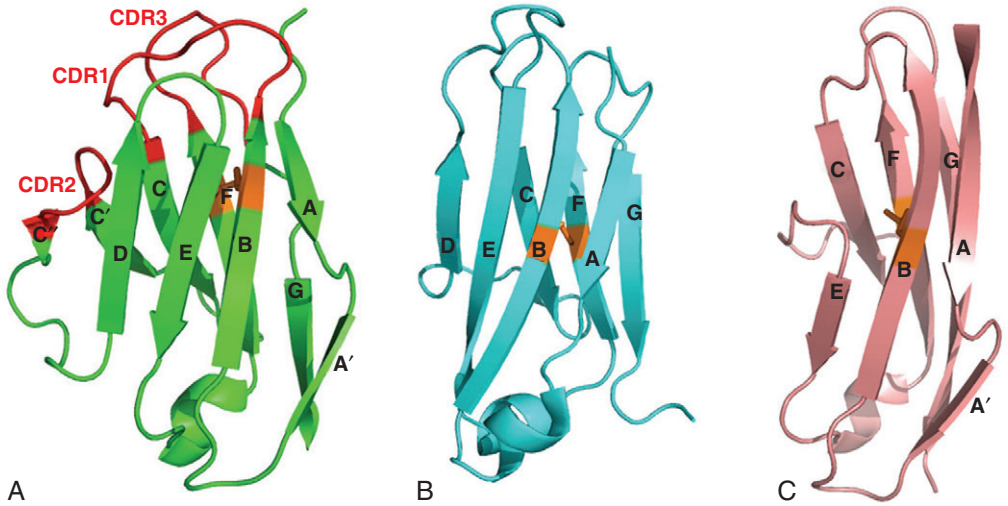

Figure 5-3 Ig DOMAIN TYPES. **A,** V-set Ig domain (PDB entry 3IDG). **B,** C-set Ig domain (3IDG). **C,** I-set Ig domain, which can be described as a truncated V-set (PDB entry 2V5M). Highlighted in orange are the disulfide bonds.

element, positioned to extend from the plasma membrane for ligand binding, serving a role analogous to antigen recognition. By contrast, I-set Ig-like domains (see Fig. 5-3, *C*) usually function as one of the building blocks lined up in tandem to present the ligand-binding V-set domain on the cell surface. This can be seen in many immune receptors such as CD2[20] and CD4.[21] There is also a large pool of receptors that are exclusively composed of I-set domains, including immune receptor ICAM1 (intercellular adhesion molecule 1),[22] neural cell adhesion molecule (NCAM),[23] and Down syndrome cell adhesion molecule (Dscam).[24,25] Thus the I-set variant is the most abundant Ig-like domain and plays a critical biologic role in cell surface receptors.

The Protein Kinase Domain

Protein kinases catalyze the transfer of a phosphate group from ATP to specific sites on target proteins. More than 500 protein kinases have been identified in the human genome. Approximately 90 of these are tyrosine kinases; the remaining protein kinases are specifically phosphorylate serine or threonine residues. Both ser/thr and tyrosine kinases share a conserved bilobed protein fold, composed of a smaller N-terminal subdomain (N-lobe) and larger C-terminal subdomain (C-lobe).[26] The active site cleft, including the site for binding the substrate ATP, is found at the interface between the N- and C-lobes. The phosphate-coordinating "P-loop" is a portion of the β sheet in the N-lobe that coordinates the triphosphate moiety of ATP. The activity of protein kinases is typically regulated by phosphorylation on a loop in the C-lobe termed the *activation loop* or *A-loop*. In the absence of phosphorylation, the A-loop may play an inhibitory role, sometimes blocking binding of ATP in the active site, or it may be disordered altogether. Upon autophosphorylation, or phosphorylation in *trans* by an upstream activating kinase, the activation loop rearranges to adopt a characteristic hairpin conformation that creates the site for docking of the polypeptide segment that will become phosphorylated. Activation loop phosphorylation may also induce other structural rearrangements required for catalytic activation, in particular a reorientation of a helix within the N-lobe (known as the C-helix) that brings a glutamic acid residue into proper position within the active site (Fig. 5-5, *A*).

Deregulated tyrosine kinases are the cause of a number of hematologic malignancies. Two general classes of tyrosine kinases can be defined: receptor and nonreceptor tyrosine kinases. Receptor tyrosine kinases are transmembrane proteins with an extracellular ligand-binding domain—often composed of Ig-like domains as described earlier, a single transmembrane domain and the cytoplasmic tyrosine kinase domain. They are generally activated by dimerization upon binding of ligands to their extracellular region, which induces autophosphorylation and activation of their catalytic domains inside the cell.[27] Chromosomal translocations that underlie a number of human leukemias fuse a tyrosine kinase domain to an oligomerization domain from an otherwise unrelated protein, often the dimerization domain of a transcription factor, to generate a constitutively dimeric, and therefore constitutively active, kinase. Examples of such oncogenic translocations include (1) the fusion of the dimerization domain of an ETS-family transcription factor to a JAK-family tyrosine kinase in the leukemogenic TEL-JAK2 fusion[28] and (2) the fusion of the oligomerization domain of nucleophosmin with the tyrosine kinase domain of ALK in the NPM-ALK fusion in anaplastic large-cell lymphoma.[29] These translocations are further described in Chapters 54 and 72, respectively.

Perhaps the best-characterized kinase translocation is the BCR-ABL fusion protein produced by the (9;22) chromosomal translocation in chronic myelogenous leukemia (see also Chapter 66). Treatment of this disease with imatinib, a specific inhibitor of ABL, has established a paradigm for targeted therapy in cancer.[30] ABL is a nonreceptor tyrosine kinase that contains Src homology 3 and 2 (SH3 and SH2) domains in addition to its tyrosine kinase domain. Additionally, the normal ABL protein is myristoylated at its N-terminus. In the normal protein, the N-terminal region including the myristoyl group and adjacent sequences, the SH3 and SH2 domains assemble with the kinase domain to lock it in an inactive conformation (see Fig. 5-5, *B*).[31] These interactions are released to activate the kinase when the phosphotyrosine-binding SH2 domain and proline motif–binding SH3 domains bind their cognate ligands in a target protein.[32] The myristoyl group may also be release from its docking site in the C-lobe of the kinase upon activation to promote membrane localization of the protein.[33] Thus in its normal state, the various domains of ABL comprise an exquisite signaling switch that is regulated by appropriate binding interactions; in the absence of the proper targeting interactions, the kinase is maintained in an inactive state by the intramolecular associations of its domains. In the oncogenic BCR-ABL fusion protein, this regulatory control is lost because the N-terminal regulatory region is truncated and replaced with unrelated sequences from the BCR protein.

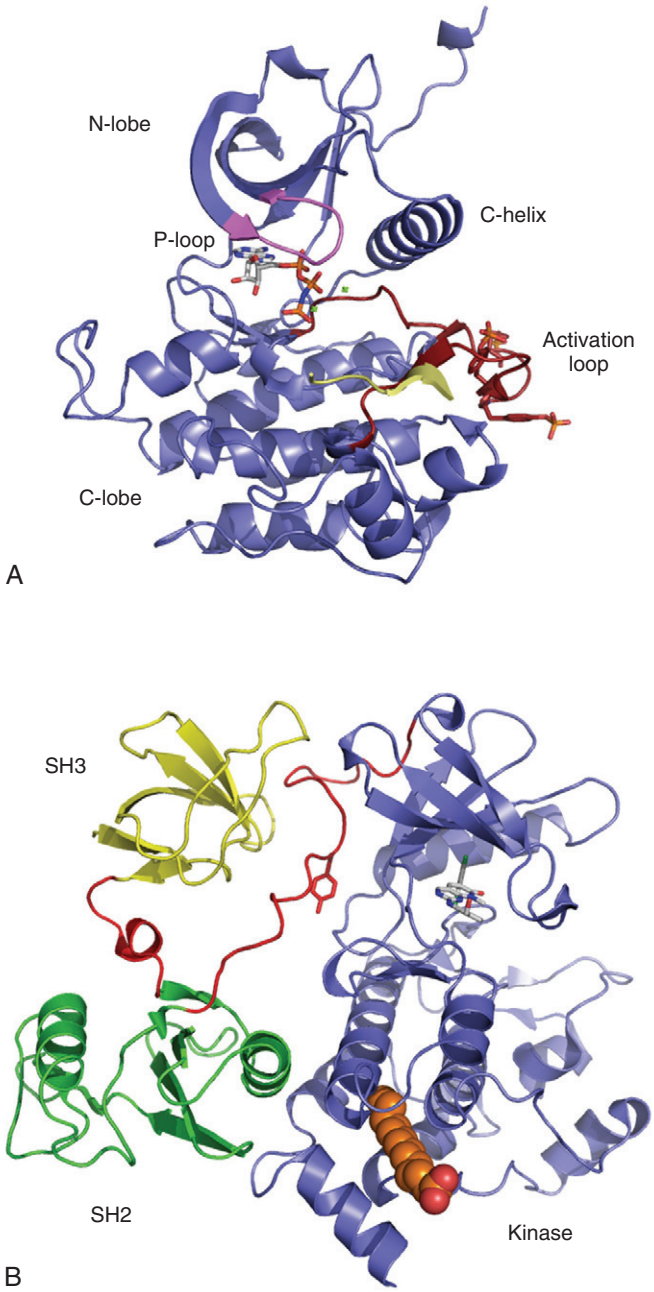

Figure 5-5 A, A kinase domain in complex with an ATP analog and peptide substrate (PDB entry 1IR3). The phosphate-binding loop is highlighted in *purple,* the activation loop is red, the substrate peptide is *yellow,* and the ATP analog is shown in *grey.* **B,** The autoinhibited structure of Abelson tyrosine kinase (c-ABL) in complex with the kinase inhibitor PD166326 (PDB entry 1OPK). The Src homology 3 (SH3), SH2, and kinase domains are shown in *yellow, green,* and *blue,* respectively. The SH2–kinase-domain linker and the SH3-SH2 connector are shown in *red.* The myristate is shown in *orange* spheres in the C-lobe of the kinase.

Molecular Interactions and Regulation of Gene Expression

Genomic DNA is packaged into chromatin, an ordered structure composed of the building block called the *nucleosome*. In each nucleosome, DNA of 147-bp wraps in two superhelical turns around a histone octamer formed by an H3-H4 tetramer and two H2A-H2B dimers. Nucleosome core particles are linked by short stretches of DNA bound to "linker" histones H1 and H5 to form a nucleosomal filament that is folded into higher-order structure of chromatin fiber. Epigenetic regulation of gene expression involves a host of protein complexes, conserved structural modules and molecular interactions mediated by DNA (i.e., methylation of cytosine) and histone modifications (i.e., acetylation, methylation, phosphorylation, SUMOylation, and ubiquitylation), which work together to compose a balanced and heritable system.[34] The addition, removal, and interpretation of these covalent chemical modifications to chromatin allow for an additional level of complex control of gene transcription beyond the genetic code. Early processes such as cell differentiation and embryonic development, as well as aging and environmental effects on mature organisms are all controlled by epigenetic processes.[35] Dysregulation of these mechanisms has been shown to lead to cancer and other diseases. Manipulating the occurrence of these modifications has therefore inspired new clinical therapies. Toward this goal, many studies have focused on examining functional mechanisms of the proteins that are involved in chromatin remodeling and epigenetic control of gene transcription at a molecular and structural level.

Notably, many chromatin-associated proteins contain one or more structurally conserved domains that are, for the large part, exclusive to chromatin remodeling and may recognize DNA, RNA, or covalent histone modifications. Few of these domains occur or behave alone; many are found in multiple copies or in tandem with other chromatin-associated domains in a single protein. Contrary to the earlier "histone code hypothesis," which postulated that different combinations of modifications, either in combinatorial or sequential manner, can elicit different transcriptional outcomes by recruiting proteins that recognize these modifications,[36,37] mounting evidence from recent studies show that these histone modifications work in combination and exert context-dependent functions in control of gene transcription in chromatin, thus allowing for a far more nuanced functional response.[38]

Of all the known histone modifications, lysine acetylation and methylation are best characterized thus far for their role in control of gene transcription through modification-dependent interactions with the modular domains present in chromatin and transcription-associated proteins. Lysine acetylation by HATs, such as Gcn5, PCAF, TAFII250, and CBP/p300, serves as a means to facilitate protein complex assembly through binding to the bromodomain (BrD), which until very recently (see later) was the only known acetyl-lysine binding domain.[39] Originally identified in the *Drosophila* protein brahma (hence the name),[40] the bromodomain is a conserved module found in many chromatin-associated proteins and HATs.[41] Structural analysis of the bromodomain from PCAF reveals that the bromodomain structure consists of a left-handed 4-helix bundle in which loops connecting the helices form the acetyl-lysine binding pocket (Fig. 5-6, *A*). The functions of bromodomains in gene transcription include directing remodeling complexes (such as the SWI/SNF, RSC, or PBAF complexes) to open chromatin for gene activation; recruitment of the bromodomain-containing HATs such as CBP/p300 for acetylation on histones and transcription-associating proteins; and facilitating the assembly of active transcription machinery complexes by transcription factors such as p53, NF-κB, and STAT3.

Chromodomains bind specifically to methyl-lysine sites on histones.[43,44] Various families of chromodomain have been defined (e.g., the "Royal Family" domains, which include the Tudor, PWWP, MBT [malignant brain tumor], and Agenet domains), but all contain a three-strand β-sheet capped on one side by an α-helix (see Fig. 5-6, *B*).[45] The chromodomain of heterochromatin protein 1 (HP1) binds to H3K9me3 to form transcriptionally silent heterochromatin. The importance of chromodomain/methyl-lysine binding is epitomized by polycomb repressive complexes (PRC1 and PRC2) in transcriptional gene silencing.[46]

An additional methyl-lysine targeting domain is the PHD finger, a small zinc-binding motif (50-80 amino acids) that appears in chromatin-associated proteins.[47] The conserved PHD fold consists of a two-stand antiparallel β-sheet and a C-terminal α-helix that is

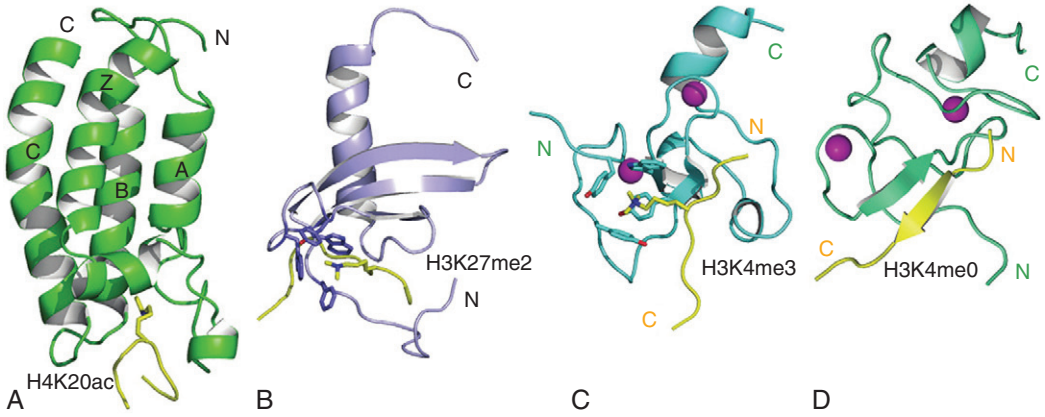

Figure 5-6 Three-dimensional structures of histone binding domains. **A,** CBP bromodomain bound to an H4K20ac peptide (PDB code: 2RNY). **B,** CBX7 chromodomain/H3K27me2 complex (PDB code: 2KMV). **C,** BPTF PHD finger/H3K4me3 complex (PDB code: 2F6J). **D,** AIRE PHD finger bound to an H3K4me0 peptide (PDB code: 2KFT).

stabilized by two zinc atoms anchored by the Cys4-His-Cys3 motif. Functional versatility of the PHD fold is underscored by the extraordinary ability of some PHD fingers to recognize histone H3 in an H3K4 methylation sensitive manner (positively or negatively), typifying it as an epigenetic "reader" module. One type of PHD finger is the human BPTF or ING2, which binds the trimethylated H3K4me3 (a mark for gene activation) in an "aromatic cage" (see Fig. 5-6, *C*).[48] Another type of PHD finger lacks this aromatic cage (e.g., AIRE or BHC80) and specifically recognizes the nonmethylated H3K4 site (a mark for gene repression) using an N-terminal aspartic acid (see Fig. 5-6, *D*).

CHAPTER 6

SIGNALING TRANSDUCTION AND REGULATION OF CELL METABOLISM

Pere Puigserver

Hematopoiesis is a cellular process in which self-renewing stem progenitor cells differentiate into mature blood cells, which carry out specific biologic functions. These functions include oxygen delivery, clot formation, and defense of the host from infection. Homeostasis of the whole hematopoietic system in vivo requires a tight control of systems and networks governing proliferation, cell fate, cell death, differentiation, cell–cell interaction, and migration. An imbalance in or dysregulation of these processes results in pathologic alterations. For example, uncontrolled cell proliferation is a signature of leukemias, and defective lymphocyte differentiation can lead to immunodeficiency. A better understanding at the molecular level of these biologic events will help to identify new therapeutic targets for the design of better drugs to treat hematologic diseases.

Because of the diversity in cellular types and their respective, specific biologic functions, hematopoietic cells respond to a broad array of extrinsic and intrinsic signals transduced through molecular (signaling and metabolic) pathways. It is therefore important to recognize that these molecular pathways serve to ultimately define a specific functional response in a given cell type. These regulatory signals (Table 6-1) can be general, such as growth factors (e.g., insulin growth factor [IGF], fibroblast growth factor [FGF]) or amino acids that control proliferation, or highly specific, such as the antigen signaling response in immune cells or 2,3-diphosphoglycerate in erythrocytes. Importantly, the action of these signals—as well as their integration inside the cell—is needed to accomplish a specific cellular task (either a physiologic or cellular fate decision). Moreover, as discussed later in this chapter, these signals also serve to tightly control metabolic pathways in hematopoietic cells, such as anaerobic glycolysis for energy generation in red blood cells (RBCs).

Extrinsic cellular signals, often polypeptides, are recognized by plasma membrane receptors that trigger a phosphorylation cascade (using tyrosine or serine or threonine residues) that propagates through the cytoplasm and cellular organelles, including the nucleus. Thus, the sequential activation of this cascade occurs in a temporal and spatial manner to define the specific biologic response. In general, there are two types of signals (Fig. 6-1): (1) signals that transduce immediate or short-term biologic outputs without changes in gene expression and (2) signals that transduce medium- and long-term biologic outputs with changes in gene expression. In the first case, for example, chemoattractants induce the PI3K and Cdc42 pathways to rapidly establish neutrophil polarity. One example in the second case is the signaling transduced through frizzled receptors and the transcription factor T-cell specific transcription factor (TCF-1) necessary for T-cell development. In both cases, the signals transduced are amplified through a series of physical interactions and chemical modifications on proteins, the most common being phosphorylation, but others such as ubiquitination, acetylation, sumoylation also play important roles.

This chapter provides a general survey of the different key signaling and metabolic pathways that operate in hematopoietic cells. The goal is to provide the molecular basis by which signals are transduced and control fundamental cellular processes that define the different lineages of the hematopoietic system.

SIGNALING TRANSDUCTION

Hematopoietic cells use general signaling transduction pathways that are common to most cell types. The specificity in these signaling transduction pathways is often established at the beginning of the pathway's activation (e.g., by specific antigen-binding or ligand-membrane receptor complexes) (Table 6-2), and at downstream targets, including transcription of the specific genes that will serve to define a particular biologic response (see Fig. 6-1). Here, we will review these general signaling transduction pathways, illustrating some of the specific components of hematopoietic cells.

Receptor Tyrosine Kinases, Phosphoinosite-3-Kinase, and Mitogen-Activated Protein Kinase Pathways

Receptor Tyrosine Kinases

Receptor tyrosine kinases (RTKs) are enzyme-linked receptors localized at the plasma membrane containing an extracellular ligand-binding domain, a transmembrane domain, and an intracellular protein-tyrosine kinase domain. In general, the ligands for RTKs are proteins such as IGF, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and FGF. Ephrins that bind to Eph receptors also form a large subset of RTK ligands. The colony stimulating-factor 1 (CSF-1), which is important for macrophage function, is another example of RTK ligand. RTKs can function as monomers or multimeric subunits assembled at the plasma membrane that, upon ligand binding, cause oligomerization or conformational changes followed by tyrosine (trans)-phosphorylation in the kinase activation loop. Activation of RTKs results in phosphorylation of additional sites in the cytoplasmic part of the receptor, leading to docking of protein substrates, which initiate the intracellular signaling cascade. These substrates bind to RTKs phosphorylated tyrosines through SH2 (Src homology domain-2) or PTB (phosphotyrosine-binding) domains. Examples of these types of proteins are insulin receptor substrates and the p85 regulatory subunit of the phosphoinosite-3 kinase (PI3K). RTKs recruit, assemble, and phosphorylate different proteins, including adaptors and enzymes.

There are mechanisms to terminate the ligand-induced RTK activity through cellular processes, including receptor-mediated endocytosis or through a family of regulated protein–tyrosine phosphatases (PTPs), some of which are transmembrane and have extracellular domains, suggesting the possibility of ligand-mediated regulation. Interestingly, there is also intracellular regulation of PTPs through negative feedback loops to attenuate the signal or direct control through reactive oxygen species (ROS) (see later discussion).

Phosphatidylinositol-3-Kinase Pathway

One of the key signaling components associated with RTKs is the phosphatidylinositol-3-kinase (PI3K) signaling transduction pathway.

This pathway is also activated by cytokine receptors and G protein–coupled receptors. Among many functions of this pathway in hematopoietic cells, the interleukin-3 (IL-3)–dependent survival of these cells largely depends on the activation of the PI3K pathway. PI3K is a heterodimeric complex formed by a regulatory and a catalytic subunit. The regulatory protein subunits are encoded by isoforms (which include p85α and p85β) that contain SH3 binding domains that mediate binding to activated RTKs. This binding allows additional recruitment and activation of the PI3K catalytic subunits (p110α, p110β, and p110*). At the plasma membrane, activated PI3K phosphorylates PIP2 (phosphoinosite-2) at position 3 of the inositol to produce PIP3. In addition, Ras, a small guanosine triphosphate (GTP)–binding protein and potent oncogene, also activates PI3K. An important lipid phosphatase and tumor suppressor, phosphatase and tensin homologue (PTEN), dephosphorylates PIP3, counteracting PI3K and decreasing the intensity of the pathway. Accumulation of PIP3 at the plasma membrane recruits several pleckstrin homology domain (PHD) containing proteins, among them PDK and AKT serine/threonine kinases, which are key components in transducing the PI3K signaling. Activated AKTs target different protein substrates for initiation of a biologic response. For example, the Bad protein, phospho-Bad does not bind Bcl-2 and functions as an anti-apoptotic mechanism and promoting cell survival. Another key target of AKTs are the forkhead transcription factors FoxOs (Fig. 6-2). When phosphorylated by AKT, phospho-FoxOs are sequestered and inactive in the cytoplasm through direct binding to 14-3-3 proteins. Dephosphorylated FoxOs, on the other hand, activate gene expression associated with stress resistance and cell growth arrest. Another major component downstream of AKT is mTOR (mammalian target of rapamycin, a kinase that belongs to the phosphoinositide 3-kinase related protein kinases family), which is involved in metabolism, growth and proliferation. Akt phosphorylates TSC2 that forms a complex with TSC1 decreasing its GTPase activating protein (GAP) activity for small GTPase Rheb, as a consequence increases in GTP-Rheb activate mTORC1 (one of the mTOR complexes). Among the key downstream targets of mTOR are S6K and 4EBP1, which control

Table 6-1 Signals in the Hematopoietic System

Types of Ligands	Examples
Peptide or Protein	
Soluble	Growth factors or cytokine
ECM	Fibronectin, collagen
Cell surface bound	ICAM, Kit ligand
Small organics	Thyroid hormone
Nucleotides	
Soluble	ADP
DNA	Double-strand breaks
Lipids	Eicosanoids, LPA
Gases	H_2O_2, nitric oxide*

ADP, Adenosine diphosphate; *ECM,* extracellular matrix; *ICAM,* intercellular adhesion molecule; *LPA,* lipopolysaccharide.
*Function in hematopoietic system not well-defined.

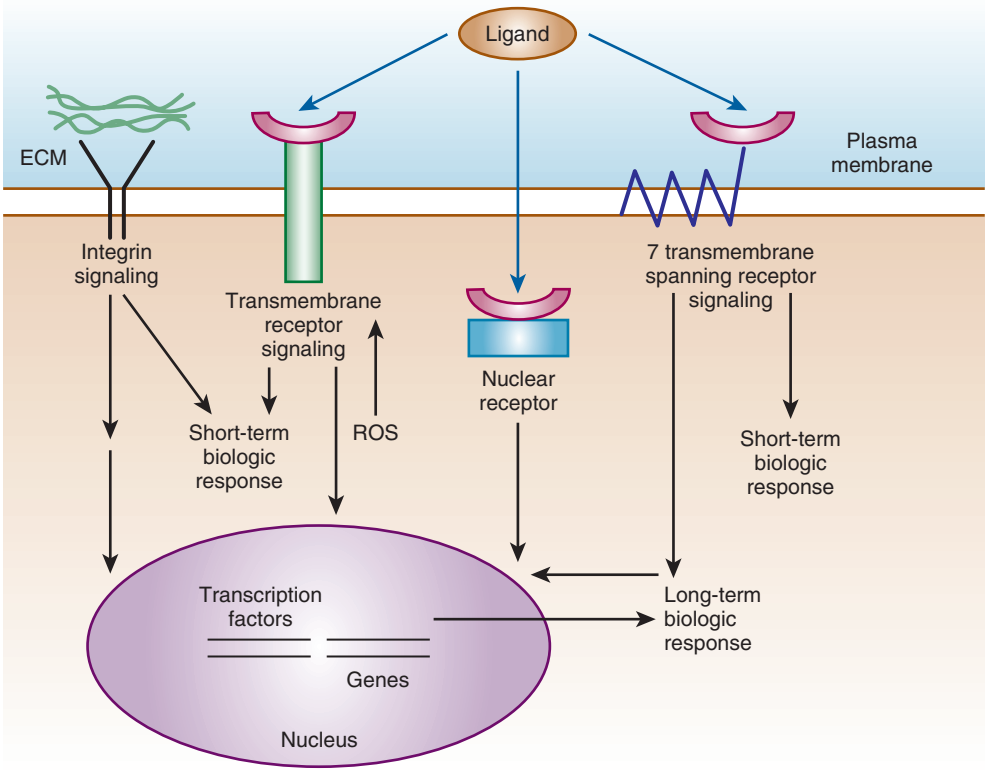

Figure 6-1 EXAMPLES OF LIGANDS AND RECEPTORS THAT TRANSDUCE BIOLOGIC RESPONSES. Signals can originate from fixed ligands (e.g., extracellular matrix [ECM]) or soluble ligands that are not membrane permeable bind to extracellular regions of transmembrane receptors. Membrane-permeable ligands bind to intracellular receptors, such as the nuclear receptor family. Signals can also originate from within the cell, such as increases in reactive oxygen species (ROS) levels. These signals cause short short-term biologic outputs without changes in gene expression or transduce medium- and long-term biologic outputs with changes in gene expression.

Table 6-2 Receptors in the Hematopoietic System

Types of Receptors	Examples	Types of Ligands
RTK	Insulin, Kit, Fms	Kit ligand, M-CSF
RSK	TGFβ receptors	Activin, BMPs, TGF-β
GPCR	Thrombin receptor, CXC, CC receptors	Thrombin chemokines
PTK-associated MIRR	Cytokine receptors BCR/TCR/FcR	Epo, interleukins, IFN peptide/MHC, Fc domains
TNF family	Fas, TNFR, CD40	Fas, TNF, CD40L
Notch	Notch	Delta-serrate-LAG-2
Frizzled family	Wnt receptors	Wnts
Toll receptors	TLR1-10	Bacterial DNA, LPS
RPTP	CD45	Unknown
Nuclear receptors	AR, RAR	Testosterone, retinoids
Adhesion receptors	Integrins	Fibronectin, collagen

AR, Androgen receptor; *BCR,* B-cell antigen receptor; *BMP,* bone morphogenetic protein; *CC,* CXC, types of chemokine receptors; *CD40L,* ligand for CD40; *Epo,* erythropoietin; *FcR,* receptors for Fc portion of antibodies; *GPCR,* G protein–coupled receptor; *LPA,* lipopolysaccharide; *M-CSF,* macrophage colony-stimulating factor; *MIRR,* multichain immune recognition receptor; *RAR,* retinoic acid receptor; *RPTP,* receptor protein-tyrosine phosphatase; *RSK,* receptor serine kinase; *RTK,* receptor tyrosine kinase; *TCR,* T-cell antigen receptor; *TGFβ,* transforming growth factor β; *TNF,* tumor necrosis factor.

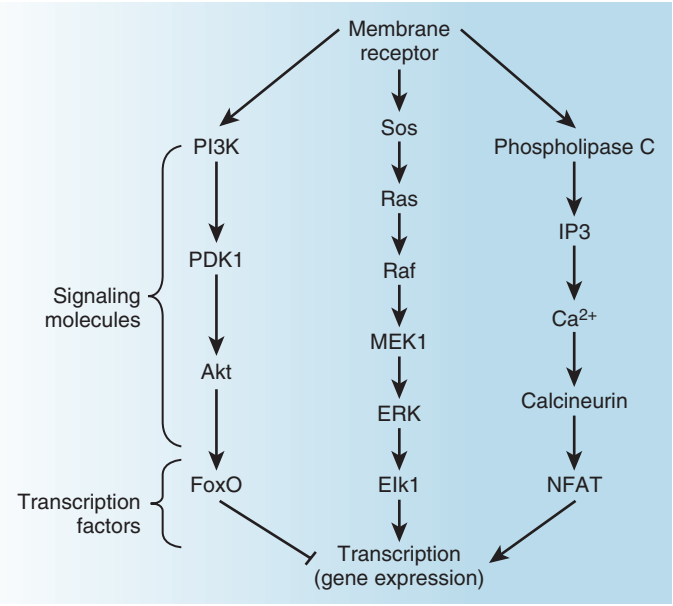

Figure 6-2 EXAMPLES OF SIGNALING AND TRANSCRIPTIONAL PATHWAYS PROGRAMMING GENE EXPRESSION. Proteins involved in gene expression are a common target of many signaling pathways, and receptors often stimulate multiple pathways that can regulate common and distinct transcription factors. In the examples shown here, production of PtdIns-3,4,5-P3 by phosphoinositide 3-kinase (PI3K) leads to the activation of the serine/threonine kinase Akt. Akt phosphorylates and inactivate FoxO transcription factors. Ras is activated by the guanine nucleotide exchange factor son of sevenless (Sos). Ras activation initiates a cascade of serine/threonine kinase activity: Ras activates Raf, Raf phosphorylates and activates MEK1, and MEK1 phosphorylates and activates extracellular signal-related kinase (ERK). Phosphorylation of the transcription factor Elk1 by ERK activates gene expression. Increased intracellular calcium is also a common signaling event. Activation of phospholipase C leads to hydrolysis of PtdIns-4,5-P2 and production of IP3. IP3 binds to its receptor, leading to intracellular calcium release and then extracellular calcium influx. Calcium activates the serine phosphatase calcineurin, which dephosphorylates nuclear factor of activated T cells (NFAT proteins), allowing them to enter the nucleus and stimulate transcription.

protein translation. mTOR can also be activated independently of RTKs through nutrients, including branched chain amino acids. Interestingly, mTORC1 inhibitors such as rapamycin are used as immunosupressors in organ transplantation.

MAPK/ERK Pathway

Activated RTKs recruit docking proteins, such as Grb2 and SOS, that allow binding of GTP to Ras to become active and trigger a kinase cascade signaling. Ras activates RAF kinase, which in turn triggers a series of MEK kinases, which finally activate mitogen-activated protein kinase (MAPK) or extracellular signal-related kinase (ERK) . ERK phosphorylates many proteins involved in cell growth, including ribosomal S6K, which is involved in protein translation and AP-1 and c-myc transcription factors, which increase many different cell cycle and antiapoptotic related genes (see Fig. 6-2). Other MAPKs include the stress-activated kinases c-Jun-terminal kinase (JNK) and p38. Constitutive MAP kinase in hematopoietic stem cells is known to induce myeloproliferative disorders.

Transforming Growth Factor-β Pathway

The transforming growth factor-β (TGFβ) family of cytokines contains two subfamilies, the TGFβ/activin/nodal and the BMP (bone morphogenetic protein)/GDF (growth and differentiation factor)/MIS (Müellerian inhibiting substance) subfamilies. At the plasma membrane, TGFβ ligands bind with high affinity to the ectodomain of type II receptors, which then recruit type I receptors. This forms a large ligand–receptor complex involving a ligand dimer and four receptor subunits. Upon ligand binding, the type II receptor phosphorylates multiple serine and threonine residues in the cytoplasmic GS-rich region of the type I receptor, leading to its activation. The phosphorylated TGFβ type I receptor binds to and phosphorylates Smad2 and Smad3 transcription factors, which are critical mediators of TGFβ signaling and function. Upon phosphorylation, Smad proteins translocate to the nucleus to activate gene expression through binding to specific DNA-binding sites. There are several mechanisms to terminate Smad activation that include proteasomal degradation and dephosphorylation. TGFβ-1 has been shown to be associated with active centers of hematopoiesis and lymphopoiesis in developing fetuses.

Signaling Through Receptors Associated With Protein-Tyrosine Kinases

Three different types of receptors and their signaling are discussed here: (1) cytokine receptors, (2) multi-chain immune recognition receptors, and (3) Integrin receptors.

Cytokine Receptors and JAK Signaling

The cytokine receptor superfamily mediates many of the central specific responses in hematopoietic cells. Ligands for these receptors include interleukins, thrombopoietin, erythropoietin, and so on. Cytokine receptors possess a conserved extracellular region (cytokine receptor homology domain [CDH]) and several structural modules, including extracellular immunoglobulin or fibronectin type III-like domains, transmembrane domain, and intracellular homology regions. Based on the divergence of the CHD, cytokine receptors are

classified in two classes, class I and class II receptors. Class I receptors contain two pairs of cysteines linked through a disulfide bond and a C-terminal WSXWS motif within the CHD. This class is further subdivided into three families, IL-2R, IL-3R, and IL-6R. All three receptor families share similar receptor chains. The class I cytokine receptors are formed by one chain containing two motifs which transduce the signaling through binding to JAK (Janus activated kinase; see later discussion). Also included in this class are the homomeric receptors that form homodimers upon ligand binding. Examples of these receptors include the erythropoietin, thrombopoietin, prolactin, and growth hormone receptors. Class II receptors also have two pairs of cysteines but lack the WSXWS motif found in class I receptors. There are pools of 12 class II receptor chains that are capable of forming a total of 10 receptor complexes. This class is functionally divided into antiviral receptors (three receptor complexes that bind interferons [INFs]) and non-antiviral receptors, which bind to several interleukins such as IL-10 and IL-20.

The oligomeric structures of cytokine receptors are complex and cannot be generalized. Cytokine binding often induces oligomerization that activates protein tyrosine kinases in the JAK family that are constitutively associated with the Box 1 and 2 motifs of the cytokine receptor. Oligomerization brings JAKs in close enough proximity to transphosphorylate on Tyr residues. This activates the JAK, which results in the phosphorylation of other cytokine receptors as well as other substrate proteins. Among these substrates, the STAT (signal transducers and activators of transcription) family of transcription factors is pivotal to JAK-mediated cytokine signaling. STATs are phosphorylated on Tyr residues by JAKs upon cytokine binding to the receptor. Phospho-STATs homo- or heterodimerize and translocate to the nucleus to activate gene expression. STATs are also phosphorylated on a serine residue via MAPK, which serves to strengthen the intensity of the signal. As part of the cytokine signaling attenuation, STATs induce genes encoding for SOCS (suppressors of cytokine signaling) proteins that bind to phosphotyrosine residues of the cytokine receptor and JAK through SH2 binding domains.

Multichain Immune Recognition Receptors

This family of receptors include antigen receptors in B and T lymphocytes, activating receptors in natural killer (NK) cells, and immunoglobulin E (IgE) and Fc receptors. This class of receptors contains different integral membrane subunits that bind the ligand at the cell surface and transduce the signal. Ligand-binding induces oligomerization of receptor subunits that contain immunoreceptor tyrosine-based activation motifs (ITAMs) within their cytoplasmic domains. These domains become phosphorylated on tyrosine residues upon receptor activation. These phosphotyrosines are involved in activation of a series of protein tyrosine kinases containing SH2 domains that include Src (SFK), Syk (Syk or ZAP-70), and Tec (Btk, Itk, Rlk) that mediate immune signaling through downstream pathways that include MAPK, calcium signaling and nuclear factor kappa-B (NF-κB), among others. The precise mechanism of this activation is not completely understood, and in some cases, such as T-cell receptors, a protein tyrosine phosphatase (-CD45, which counteracts the action of SFKs) is regulated upon ligand binding. In the case of Tec kinases, additional downstream targets include enzymes such as phospholipase C γ (PLCγ).

Integrin Signaling

Integrin receptors are involved in cell adhesion, migration, survival, and growth. This signaling is central in hematopoietic cell function, such as at places of inflammation or infection, wherein integrins trigger a cascade that by which leukocytes exit the vasculature. Interestingly, these receptors signal bidirectionally through the plasma membrane in pathways referred to as *inside-out* and *outside-in signaling*. Integrins are a class of receptors that are heterodimeric type I transmembrane proteins consisting of α and β subunits. These subunits contain a large extracellular domain, a single transmembrane domain, and a short cytoplasmic tail. There are 18 α and 8 β subunits that are associated and form 24 different integrins with different affinities for ligands. Most of the ligands are extracellular membrane (ECM) proteins containing one of the two motifs, arginine–glycine–aspartate (RGD) or leucine–aspartate–valine (LDV). Examples of integrin ligands are intercellular adhesion molecule 1 (ICAM-1), which is present at the plasma membrane of antigen-presenting cells and binds to the integrin receptor LFA-1 to promote cell–cell adhesion.

Ligand binding to the extracellular domain induces clustering of integrins, allowing separation of the different subunits cytoplasmic portions forming interactions with cytoskeleton proteins involved in actin polymerization (outside-in signaling). Signals arising from the cellular interior, including phosphorylation, can also separate these cytoplasmic domains and can affect ligand binding (inside-out). Ligand binding to integrin receptors also signals to protein tyrosine kinases such as the Src family kinases (SFK) and focal adhesion kinase (Fak). This part of the signaling is not completely understood but appears to involve a domain in the β-integrin tail (NPXY motif) that binds talin, which in turn recruits paxillin that binds Fak, which once activate phosphorylates SFKs to mediate integrin response.

Tumor Necrosis Factor Receptors and Signaling

Tumor necrosis factor receptors (TNFRs) influence inflammation, innate immunity, lymphoid organization, and T-cell responses. There are approximately 19 different ligands for TNFR that mediate cellular responses through 29 TNFRs. TNFRs are a family of single membrane-spanning proteins that contain an extracellular TNF binding region and a cytoplasmic tail. As in the case of other cytokine receptors, ligand binding causes oligomerization and the formation of a mature receptor complex that is required to transduce the signal. TNFRs fall into three classes: (1) death domain (DD) containing receptors (FAS, TNFR,1 and DR3), which activate the caspase cascade via the DD-initiating extrinsic apoptotic pathway; (2) decoy receptors, which lack the cytoplasmic tail and therefore cannot transmit the signal, making these receptors ligand sequesters; and (3) TNFR-associated factor (TRAF) receptors such as TNFR2, which lack the DD recruiting TRAF proteins. In general, TRAFs are associated with either proapoptotic or survival pathways through activation of the NF-κB family of transcription factors and MAPK signaling (ERK, JNK, and p38). TRAFs activate NF-κB through ubiquitin-mediated degradation of its inhibitor IκBα, which retains NF-κB inactive in the cytoplasm. This process is initiated by phosphorylation of IκBα by IκBα kinase (IKK) complex, mainly by the IKKb catalytic subunit, and requires a regulatory subunit (also known as NEMO [NF-κB essential modulator]). Upstream of IKKs are other kinases, including NF-κB–inducing kinase (NIK) that binds to TRAFs. Nuclear activated NF-κB modulates gene expression that mediates TNF biologic responses.

Toll-like Receptors and Signaling

Toll-like receptors (TLR) play essential roles in the innate immune response. Ten TLRs have been identified and can be grouped into two classes based on their extracellular domain: (1) TLRs with leucine-reach repeats and (2) TLRs with immunoglobulin domains. The ligands for TLRs are diverse and include the different constituent components of microorganism, such as lipopolysaccharide, and heat shock proteins (which bind to TLR2 and TLR4). The host defense against organisms mainly relies on signals originated from the TIR (Toll/IL-1) intracellular domain (domain present in TLR and IL-1R). The TLR signaling pathway is similar to the one triggered by the IL-1R. Ligand-binding induces TLR multimeric receptor complexes, recruiting adaptor proteins such as MyD88, which contains a TIR domain and a DD that in turn binds to the IRAK (IL-1R-associated kinase). IRAK is activated by phosphorylation and then associates

with TRAF6, leading to activation of mainly two different pathways, JNK and NF-κB, to activate the innate immune response, including release of inflammatory cytokines.

Wnt Signaling

Wnt proteins are lipid-modified, secreted proteins of approximately 400 amino acids that bind to Wnt cell surface transmembrane receptors, called frizzled (Fz), to initiate the canonical Wnt signaling transduction pathway. At the plasma membrane, binding of Wnt ligands to Fz receptors connect through direct binding to several intracellular proteins, including disheveled (Dsh), glycogen synthase kinase-3β (GSK3β), axin, and adenomatous polyposis coli (APC) inhibiting proteasomal-mediated degradation of the transcriptional protein β-catenin. This degradation is regulated through a GSK3β-mediated phosphorylation of β-catenin. As a consequence, β-catenin accumulates in the cytoplasm and translocates to the nucleus, where it interacts with transcription factors such as lymphoid enhancer-binding factor 1 (LEF-1)/TCFTCF to modulate gene expression.

Notch Signaling

Notch ligands are plasma single-pass transmembrane proteins named delta-like and jagged. Thus, cells expressing the ligands are adjacent to cells expressing the Notch receptors, which are also transmembrane proteins. Notch receptor interacts with a Notch ligand on a contacting cell; this interaction produces a Notch receptor cleavage that releases the Notch intracellular domain (NICD). NICD translocates to the nucleus, where it binds to several DNA binding proteins, including CBF1/suppressor of hairless/LAG-1 (CSL). As a result of this interaction between NICD and CSL, changes in Notch target genes occur. In contrast to the other signaling pathways discussed in this chapter that mainly function through phosphorylation, there is no amplification from the initial Notch ligand binding to the receptor. Moreover, this core pathway is modulated through auxiliary proteins that influence the response to the Notch ligand. Among these proteins are acute myeloid leukemia 1 (AML1), discoidin domain receptor family (DDR1), NECD, Notch extracellular domain, and CBF1 interacting protein.

Nuclear Hormone Receptor Superfamily

Nuclear hormones include steroid hormones (sex hormones, glucocorticoids, and mineralocorticoids), sterol hormones (vitamin D and its derivatives), thyroid hormones, and retinoids. These hormones are lipophilic and need carrier proteins to be transported in the blood. Because of this hydrophobicity, they can diffuse across the plasma membrane to reach the receptor proteins inside the cells, either in the cytoplasm or in the nucleus. These receptors are called the nuclear hormone receptor (NHR) superfamily. What distinguishes this receptor family from those discussed previously is their ability to directly bind to DNA and coordinate gene expression, which effectively makes them a form of transcription factor. NHRs contain a central DNA-binding domain, which targets the receptor to DNA sequences known as hormone response elements. In addition, the C-terminal part of the receptor contains a ligand-binding domain where the ligand or hormone binds. Upon ligand binding, nuclear hormone receptors control expression of diverse sets of genes related to the hormonal response. Based on the types of ligands that they can bind, NHRs can be grouped into four classes: (1) steroid receptors, which include receptors for glucorcorticoids (GRs), mineralocorticoids (MRs), progesterone (PR), androgen (AR), and estrogen (ER); (2) RXR (retinoid X receptor) heterodimers, such as thyroid receptor (TR), retinoic acid receptor (RAR), vitamin D receptor (VDR), and peroxisome proliferator activated receptors (PPARs); (3) dimeric orphan receptors, such as COUPTF and HNF4; and (4) monomeric orphan receptors, such as NGFI. The cognate ligands for orphan receptors have yet to be identified.

G Protein–Coupled Receptor and Chemokine Signaling

GPCR Signaling

The G protein–coupled receptor (GPCR) superfamily comprises a large collection of proteins, with approximately 2000 annotated genes in the human genome (≈10% of the entire genome). GPCRs are involved in a large array of physiologic functions, including platelet aggregation and leukocyte chemotaxis. GPCRs are single polypeptides with seven-pass transmembrane domains containing both cytoplasmic and extracellular regions. Ligands for GPCRs are very diverse and include proteins or peptides, amino acids, lipids, and nucleotides that bind at the cell surface where GPCRs are localized. Despite its vast size and variety of activational ligands, the GPCR superfamily relies on three main intracellular signaling cascades for communicating receptor activation: the cAMP (cyclic adenosine monophosphate)–protein kinase A (PKA), the phosphatidylinositol–phospholipase C, and the Rho GTPase-based cascades.

G protein–coupled receptors are coupled to a heterotrimeric G protein formed from three unique subunits (α, β, and γ), which are membrane bound. The G-α subunit contains a GTPase domain, which is capable of hydrolyzing guanosine triphosphate (GTP) to guanosine diphosphate (GDP). When bound to GDP, the complex is functionally inactive, with the G-α subunit remaining tightly associated with the other subunits of the GPCR complex. Upon ligand binding to the GPCR, structural conformational changes produce release of GDP from the heterotrimeric complex, allowing GTP to bind to the G-α subunit. In this GTP-bound form, G-α subunit dissociates from G-β and G-γ subunits with which it interacts. The G-α subunit then proceeds to interact with its downstream cognate targets to affect a particular signal response, depending on the GPCR and the specific G-αsubunit isoform. Among these second-messenger effectors are the cAMP–PKA pathway, ion channels, Rho GTPase, MAPK, PI3K, and InsP3–DAG (inositol 3-phosphate–diacylglycerol) pathways. In the case of the cAMP pathway, adenylate cyclase is downstream of different GPCRs (e.g., adrenergic receptors) and is activated by GTP-bound G-α. Adenylate cyclase converts adenosine triphosphate (ATP) to cAMP, a freely diffusible second messenger molecule. A key effector of intracellular cAMP is PKA, an inactive tetrameric protein complex consisting of two regulatory and two catalytic subunits. Binding of cAMP to the regulatory subunits causes release and activation of the catalytic subunits that phosphorylate different cellular targets. Among them are the transcription factor cAMP-responsive element (CREB) and several ion channels. In addition to adenylate cyclase, there are other common effectors downstream of GPCRs, such as phospholipase C, a plasma membrane bound enzyme that cleaves phosphatidyl inositol, PIP2, in two products and messengers; inositol triphosphate (IP3); and DAG. IP3 can diffuse through the cytoplasm and bind receptors in the endoplasmic reticulum, resulting in calcium release to the cytoplasm. Importantly, calcium propagates the signaling cascade through different proteins such as calcineurin and nuclear factor of activated T cells (NFAT) transcription factors (see Fig. 6-2), which are involved in, for example, IL-2 gene expression. DAG at the plasma membrane binds and activates, in conjunction with calcium, protein kinase C (PKC), which phosphorylates other downstream targets. Rho guanine nucleotide exchange factor (RhoGEF) is also a target for some G-α subunits. Binding of the G-α subunit to Rho allosterically activates its, causing GTP to be preferentially bound. This in turn allows RhoGEFs to activate Rho kinase, which is involved in the cytoskeletal reorganization necessary for changes in cell shape and motility.

Chemokine Signaling

Chemokines mediate cell migration in immune surveillance, inflammation, and development. There are nearly 50 human chemokines divided into four families (CXC, CC, C, and CX3C) on the basis of the pattern of internal cysteine residues; thus, C stands for cysteine

and X/X3 stands for one or three noncysteine amino acids. Expression of some of these chemokines is induced by inflammatory signals such as TNF-α, INF-γ, trauma, or microbial infection. There are approximately 20 signaling chemokine receptors, and they are all GPCR receptors; thus, the chemokine acts as a ligand and activation of the chemokine receptor follows the principles described above. The major downstream effectors are cAMP and calcium messengers. Interestingly, some of the chemokine receptors also bind HIV viral proteins.

REGULATION OF CELL METABOLISM

There are three important general pathways by which metabolism impact cellular function (Fig. 6-3): (1) activity of catabolic pathways that supply energy in the form of ATP, such as glycolysis or oxidative phosphorylation; (2) activity of anabolic pathways that synthesize molecules that are used for cellular growth or an specific function; and (3) generation of metabolites that control cellular intrinsic and extrinsic activities. This regulation is intimately connected to signaling transduction because most of the pathways described in the previous section directly control cellular metabolism. Here, this part of the review covers the main metabolic pathways, taking into consideration their implications in hematopoietic cells.

Glucose Metabolism

Glucose is the one of the three basic macronutrients and certain cells such RBCs, because they are devoid of mitochondria, entirely depend on glucose or other monosaccharides as an energy source. Hematopoietic cells have different types of glucose transporters (e.g., activation of T cells) that cause dramatic increases in Glut1 expression to maintain immune homeostasis. After transport into the cell, glucose is metabolized through different biochemical pathways to provide energy and building blocks for macromolecules that constitute the cell or regulatory metabolites. Glucose can be stored in cells in form of glycogen, which constitutes a rapid source of energy through its breakdown to free glucose (glycogenolysis), although this pathway is limited to certain number of hematopoietic cells. Chemotaxins (FMLP, C5ades arg, arachidonic acid) activate granulocytes to catabolize significant amounts of endogenous glycogen.

Glycolysis

Glycolysis is a series of reactions by which six-carbon glucose is converted into two three-carbon ketoacids (pyruvate). Importantly, these oxidative reactions generate energetic molecules such as ATP and NADH (nicotinamide adenine dinucleotide) and can occur in the absence of oxygen and mitochondria. In some cells such as erythrocytes, anaerobic glycolysis produces lactate, but in most cell types, pyruvate is completely oxidized to acetyl coenzyme-A and carbon dioxide by the mitochondrial pyruvate dehydrogenase complex and the tricarboxylic acid (TCA) cycle coupled to oxidative phosphorylation. In general, whereas hematopoietic stem cells are thought to largely depend on glycolysis, more differentiated cells, except for erythrocytes, use mitochondrial oxidative metabolism. Glycolytic fluxes are under intrinsically tight control through intermediate metabolites in the pathway. The most powerful control is exerted by

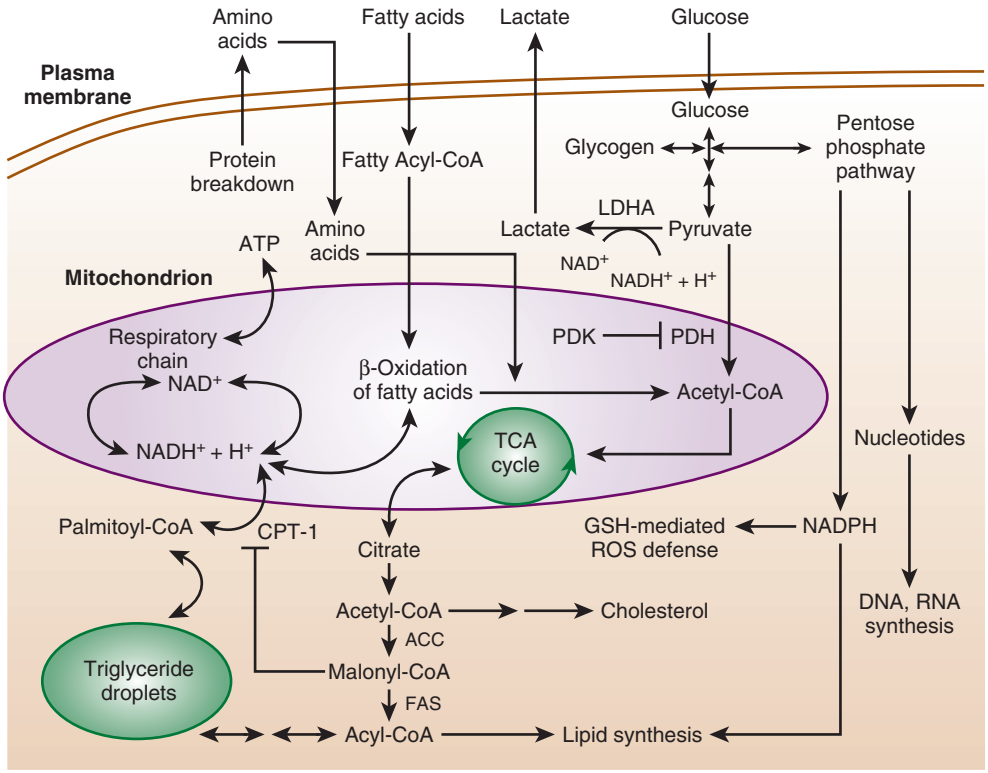

Figure 6-3 INTEGRATION OF CENTRAL METABOLIC PATHWAYS. The metabolic fluxes within anabolic and catabolic routes are controlled by different signals, including metabolite concentrations. These metabolic pathways are localized in different cellular compartments to adequately provide cellular energetic and nutrient homeostasis necessary for growth and survival. See text for further details. *ACC,* Acetyl-CoA carboxylase; *ATP,* adenosine triphosphate; *CPT-1,* carnitine palmitoyltransferase I; *FAS,* fatty acid synthase; *NAD,* nicotinamide adenine dinucleotide; *NADH,* nicotinamide adenine dinucleotide, reduced form; *PDH,* pyruvate dehydrogenase; *PDK,* pyruvate dehydrogenase kinase; *TCA,* tricarboxylic acid.

fructose 2,6-bisphosphate (F-2,6-BP), which is generated by phosphofructokinase 2. F-2,6-BP allosterically activates phosphofructokinase, providing a "feedforward" mechanism of stimulation. Activation of growth factor signaling pathways potently stimulate glycolysis at different points, including phosphorylation of phosphofructokinase 2 and pyruvate kinase. The PI3K pathway is a major signaling pathway that controls glycolysis.

Interestingly, in erythrocytes, 1,3-diphosphoglycerate can be diverted from glycolysis to synthesize 2,3-diphosphoglycerate (2,3-DPG) via the enzyme diphosphoglycerate (Rapoport-Laubering shunt). 2,3-DPG is an important metabolite that regulates oxygen binding to hemoglobin; thus, increased levels of 2,3 DPG—for example, under hypoxic conditions—allow hemoglobin to release oxygen under low partial oxygen tensions.

Pentose Phosphate Pathway

The pentose phosphate pathway (PPP) derives from glycolysis in the cytoplasm. The first enzyme in this pathway is glucose-6-phosphate dehydrogenase (G6PDH) and produces NADPH (nicotinamide adenine dinucleotide phosphate), a substrate used for lipogenesis and glutathione regeneration by glutathione reductase. The regulation of NADPH production through G6PDH is through NADPH-mediated product inhibition. The PPP is also important in generating ribose-5 phosphate, which is a precursor for nucleotide synthesis in proliferating cells. Interestingly, G6PDH deficiency leads to low levels of NADPH, which is essential for controlling reactive oxygen species through glutathione reductase. It is one of the most common erythrocyte enzymopathies, and these cells cannot prevent oxidative damage in critical molecules such as heme, causing overall irreparable damage to the cell at a much higher rate than normal, particularly in response to certain environmental triggers such as drugs and stress. The damaged erythrocytes are removed from circulation in the spleen and destroyed by macrophages at an elevated rate, leading to anemia. This enzymopathy occurs in areas with high malarial burden, partly because the mutated recessive allele confers malarial resistance. This resistance is because RBCs with low G6PDH activity, when infected with the parasite, are continuously removed from the circulation.

Tricarboxylic Acid or Krebs Cycle

A major route for pyruvate oxidation is conversion to acetyl-CoA, a reaction catalyzed by the mitochondrial pyruvate dehydrogenase enzymatic complex. Acetyl-CoA is a high-energy intermediate that can be further oxidized by the TCA cycle or used for fatty acid synthesis. The TCA cycle is initiated by the condensation of oxaloacetic acid with acetyl-CoA, forming citrate. In reactions involving decarboxylation and oxidation, CO_2 is produced, and NADH and FADH (flavin adenine dinucleotide) are produced for use in the mitochondrial respiratory chain. The flux of the TCA cycle is regulated by the levels of acetyl-CoA and oxaloacetic acid, which are entry points in the cycle, and by the availability of NAD^+ and FAD^+ substrates. The rate of oxidation through the TCA cycle depends on mitochondrial electron transport activity, which is governed in part by NADH levels. The TCA cycle also produces metabolites for biosynthetic processes (anaplerotic reactions). For example, citrate is converted to fatty acids and sterols, and succinyl CoA is an intermediate in heme and porphyrin synthesis. Aside from the bioenergetic and anaplerotic aspect of this cycle, several reactions have important clinical implications. Recently, for instance, gain-of-function mutations of isocitrate dehydrogenase 1 and 2 (IDH1 is cytoplasmic and is unrelated to the TCA cycle; IDH2 is the TCA mitochondrial form) have been found in 20% of patients with acute leukemia. In three identified mutations, the enzyme undergoes a change in its normal physiologic catalytic reaction (i.e., oxidative decarboxylation of isocitrate to produce α-ketoglutarate and CO_2 while converting NAD[P] to NAD[P]H) and instead produces 2-hydroxyglutarate, which is now considered to be an a pro-oncometabolite.

Oxidative Phosphorylation

In most cell types, oxidative phosphorylation is dominant on ATP generation. Exceptions include RBCs that lack mitochondria. Oxidative phosphorylation complexes are located at the inner mitochondrial membrane and receive high-energy electrons from NADH (produced from the oxidation of acetyl-CoA). These electrons are passed through the different oxidative phosphorylation complexes (which contain heme, copper iron-sulfur groups, and flavins as electron carriers) until they reach the final electron acceptor, molecular oxygen. As a consequence of electron transfer, protons are pumped into the mitochondrial intermembrane space, generating an electrochemical gradient used to synthesize ATP. There are five oxidative phosphorylation complexes: complex I (NADH-CoQ reductase complex), complex II (succinate–CoQ reductase complex), complex III (CoQH2–cytochrome C reductase complex), complex IV (cytochrome C oxidase complex), and complex V (ATP synthase complex). In general, hematopoietic stem cells are located in low-oxygen niches and largely depend on glycolysis instead of oxidative phosphorylation to maintain ATP levels. The differentiation process is associated with increases in mitochondria, which allow for the generation of ATP through the respiratory chain. For example, this occurs in quiescent T cells that are in a catabolic phase producing ATP mainly through oxidative phosphorylation. Upon stimulation, activated T cells shift toward an anabolic phase, relying on a high rate of glycolysis for ATP generation. Mitochondrial DNA encodes for several oxidative phosphorylation subunits and mutations in this DNA produces mitochondrial diseases. Interestingly, anemia is a symptom associated with patients having Pearson syndrome and is caused by accumulation of mutated mitochondrial DNA in sideroblasts. This suggests that hematopoietic cell–specific respiration defects can be responsible for anemia by inducing abnormalities in erythropoiesis during development.

Reactive Oxygen Species Metabolism

Reactive oxygen species (ROS) are chemically reactive small molecules with oxygen in different oxidation states, such as partially reduced oxygen ions and peroxides. The three major species are superoxide, hydrogen peroxide, and hydroxyl radicals. The major cellular sites for ROS production are the mitochondria and NADPH oxidase, a plasma membrane or phagosome-bound enzyme. Approximately 85% of cellular ROS is a subproduct of normal oxidative phosphorylation. Superoxide is the initial ROS produced in the electron transport chain and is transformed to hydrogen peroxide by the enzyme superoxide dismutase. Hydrogen peroxide is the substrate of catalase or glutathione peroxidase, which reduces it to water. Hydrogen peroxide, however, is also converted to hydroxyl radicals, the most reactive oxygen species, in a Fenton reaction with ferrous iron. NADPH oxidase catalyzes the NADPH-dependent reduction of oxygen into the superoxide anion.

Reactive oxygen species cause cellular damage through oxidation and chemical modifications of proteins, lipids, and DNA. Nuclear and mitochondrial DNA can be oxidized, producing strand breaks. Intracellular levels of ROS are regulated through different signaling transduction pathways. Growth factor–mediated signaling increases ROS levels, for instance. Conversely, ROS also affect this signaling through modulation of protein tyrosine phosphatases that contain cysteine-sensitive residues that modulate their enzymatic activity and regulate the biological responses associated with this signaling.

Reactive oxygen species are particularly deleterious to hematopoietic stem cells because of their effect on genomic stability and survival. In phagocytic cells (neutrophils, macrophages, or eosinophils), NADPH oxidase is responsible for the oxidative burst that is triggered upon phagocytosis of pathogens. Superoxide generated by NADPH oxidase is rapidly converted to other ROS, which, in cooperation with pH-sensitive proteases, are responsible for killing the microorganisms in the phagosome vacuole.

Lipid Metabolism

Fatty acids and triglycerides (storage form of fatty acids) constitute an energetic reserve in the body. Most of the cells are able to synthesize fatty acids, but essential fatty acids such as linoleic acid, α-linoleic, and arachidonic acid cannot be synthesized. Arachidonic acid is made from linoleic acid and is the precursor for prostaglandins, thromboxanes, and leukotrienes which participate in different pathways such as the inflammatory response. Drugs that block the enzyme cyclooxygenase and prostaglandin synthesis such as acetaminophen, ibuprofen, and acetylsalicylate provide pain relief. Fatty acids can directly mediate transcriptional responses acting as ligands for PPARs, a family of nuclear hormone receptors.

Fatty Acid Synthesis

In the mitochondrial matrix, acetyl-CoA is generated from pyruvate and is the precursor for fatty acid synthesis. Acetyl-CoA cannot cross the mitochondrial membrane; thus, acetyl-CoA condenses with oxaloacetate (first reaction in the TCA cycle) to form citrate and is exchanged into the cytoplasm through TCA translocases. In the cytoplasm, citrate is converted to acetyl-CoA by ATP citrate lyase. The rate-limiting reaction of fatty acid synthesis is the carboxylation of acetyl-CoA to form malonyl CoA, which is catalyzed by acetyl-CoA carboxylase (ACC). Malonyl CoA is a potent inhibitor of fatty acid oxidation. ACC is allosterically regulated by citrate to form active enzyme polymers, which are depolymerized by the end product of fatty acid synthesis: long chain fatty acids. Growth factors positively control ACC dephosphorylation. Catecholamines, on the other hand, result in the phosphorylation and inhibition of ACC via PKA. Fatty acids are synthesized in the cytoplasm by a multifunctional enzyme, fatty acid synthase (FAS). Two of these functional domains are the acyl carrier protein (ACP) and the condensing enzyme (CE). After completion of the different rounds of synthesis, the palmityl group is transferred to CoASH. In macrophages, LPS activates lipogenesis through activation of SREBP (sterol regulatory element-binding protein), a key transcriptional mediator of cholesterol and fatty acid synthesis.

Fatty Acid Oxidation

Fatty acids are "charged" before oxidation to form acyl-SCoA, a cytoplasmic reaction catalyzed by the enzyme fatty acyl-CoA synthetase. Fatty acid β-oxidation, however, occurs in the mitochondrial matrix, and charged fatty acids must first be conjugated to carnitine to cross the mitochondrial membranes. This transport is carried out by the carnitine acyltransferases I and II. These enzymes constitute a rate-limiting step for β-oxidation of fatty acids and are allosterically regulated by malonyl CoA, allowing the cell to avoid a futile cycle of fatty acid synthesis and breakdown. Inside the mitochondria, acyl-CoA undergoes a cycle of reactions removing acetyl-CoA from the main chain. This acetyl-CoA is then processed through the TCA cycle.

Cholesterol

Cholesterol is an important component of cellular membranes and is a substrate for the production of steroid hormones. Free cholesterol is tightly control in cells through synthesis, storage, and transport. Excess cholesterol in cells is secreted through reverse cholesterol transport or stored in the cytoplasm as cholesterol ester, produced by acyl-CoA: cholesterol acyltransferase located in the endoplasmic reticulum. Cholesterol is transported in plasma by lipoproteins, including chylomicrons and very low-density lipoprotein (VLDL). The main sources of cellular cholesterol for hematopoietic cells are the cholesterol-rich lipoprotein, low-density lipoprotein (LDL), and de novo synthesis from acetyl-CoA. The rate-limiting step for cholesterol synthesis is catalyzed by HMG-CoA reductase, the direct target of the cholesterol-lowering statin drugs, and converts hydroxymethylglutaryl CoA to mevalonic acid. Cellular cholesterol levels are sensed in the endoplasmic reticulum through the SREBP transcription factor, which directly controls most the enzymes in cholesterol synthesis as well as LDL transport. Excess of LDL becomes oxidized and taken by macrophages, a main cause of atherosclerosis. The SREBP pathway is also important for T-cell activation under antigenic challenge because its activation favors cholesterol synthesis and transport, which is used for membrane biogenesis and cell proliferation in the activated T cell.

Amino Acid Metabolism

The major sources of amino acids are from the diet or protein breakdown. Non-essential amino acids are synthesized from carbon skeletons using different metabolic pathways. Amino acids conjugated to tRNA are used in protein synthesis; however, in excess, they can be used for energy production. In addition, amino acids are necessary for the synthesis of other compounds. For example, tryptophan catabolism constitutes a route for de novo NAD^+ synthesis in a pathway that is important in leukocytes for the replenishment of NAD^+ levels after oxidative stress. Interestingly, different metabolites derived from tryptophan catabolism via kynurenine pathway play a role in immune tolerance. Plasma amino acids are transported in cells against a concentration gradient. Amino acid transporters are specific for neutral (small and larger), basic, and acidic amino acids. Depending on the cell type and specific state—growth, hypoxia, or fasting—intracellular amino acids are used in anabolic or catabolic pathways.

Most of the regulation of amino acid metabolism is achieved through substrate fluxes affecting specific enzyme kinetics. However, two major regulatory pathways involve amino acid–sensing mechanisms and metabolic control: (1) GCN2 (general control nonrepressed 2) is a protein kinase that senses amino acid deficiency through direct binding to uncharged tRNA. GCN2 controls the transcription factor ATF4 affecting different enzymes of amino acid metabolism. (2) mTOR (mammalian target of rapamycin) is a protein kinase activated in response to increased amino acid concentrations (particularly, branch chain amino acids). mTOR controls many aspects involved in protein synthesis, inhibition of protein degradation, and amino acid biosynthetic enzymes. The high asparagine requirement of certain acute lymphoblastic leukemias has resulted in the use of asparaginase to deplete circulating levels of asparagine. Limited amounts of asparagine result in activation of GCN2 in the leukemic cells and reduce their proliferation and viability rates.

Biosynthesis of the Non-Essential Amino Acids

Non-essential amino acids are synthesized by most of the cells, including hematopoietic lineages. Non-essential amino acids are mainly synthesized from glucose (alanine, arginine [from the urea cycle in hepatic cells], asparagine, aspartate, cysteine (from methionine) glutamate, glutamine, glycine, proline, and serine), except tyrosine, which is synthesized from phenylalanine. The rest of the nine amino acids are essential, and the body needs to obtain them from the diet. Serine, glycine, and cysteine are synthesized from glycolytic intermediates. Serine synthesis has recently been found to be increased and necessary in stem cells. For some hematopoietic cells, the synthesis of cysteine and glycine is of elevated importance because of their use in the synthesis of the tripeptide glutathione. Aspartate and asparagines are synthesized by transamination of oxalacetate by glutamate and amide transfer from glutamine respectively. Glutamate, glutamine, proline, and arginine are formed from the TCA cycle intermediate α-ketoglutarate.

Amino Acid Catabolism

Two central reactions in amino acid catabolism are the generation of ammonia through transamination (catalyzed by amino transferases) and oxidative deamination (catalyzed by glutamate dehydrogenase) in which the α-amino group of the different amino acids is transferred to α-ketoglutarate to form glutamate, which undergoes the release of free NH_3. Free ammonium is added to glutamate to generate glutamine that is then exported into circulation to the liver and enter the urea cycle. The urea cycle only occurs in the liver and has two purposes: (1) to get rid of free ammonium and (2) to supply arginine. Interestingly, one of the enzymes of the urea cycle, arginase (which converts arginine to ornithine), is expressed in immune cells. Myeloid cell arginase depletes arginine and suppresses T-cell immune response and is an important mechanism of inflammation-associated with immunosuppression. Arginase is viewed as a promising strategy in the treatment of cancer and autoimmunity. Arginine is also essential for the differentiation and proliferation of erythrocytes.

Nucleotide Metabolism

Nucleotides are involved in a diverse array of cellular functions, including (1) energy metabolism (ATP, NAD^+, $NADP^+$, and FAD^+ and their corresponding reduced forms); (2) units of nucleic acids (NTPs are substrates for RNA and DNA polymerases); (3) physiologic mediators such as adenosine, ADP (which is critical in platelet aggregation), cAMP and cGMP (second messenger molecules), and GTP (which participates in signal transduction via GTP binding proteins).

Most of the regulatory pathways that are associated with nucleotide synthesis and degradation are strictly controlled by regulatory components of the cell cycle machinery. The amount of intracellular nucleotides has to reach certain levels for the cell to proceed through the S phase checkpoint. In addition, several of the key cell cycle regulators, including the c-myc oncogene (which is translocated in certain myelomas), directly increase the expression of most of the key enzymes associated with nucleotide synthesis.

Nucleotide Synthesis

There are two pathways for the synthesis of nucleotides, salvage and de novo. The salvage pathway uses free bases by a reaction with phosphoribosyl pyrophosphate (PRPP) and generation of nucleotides. De novo pathways synthesize pyrimidines and purine nucleotides from amino acids, carbon dioxide, folate derivatives, and PRPP. Importantly, both salvage and de novo pathways depend on PRPP, which is produced from ATP and ribose-5-phosphate (generated in the pentose phosphate pathway) by PRPP synthetase, an enzyme that is inhibited by metabolic markers of low energy AMP, ADP, and GDP to avoid nucleotide synthesis in these conditions. In general, PRPP levels are low in postmitotic cells but high in proliferating cells. Folate is essential in nucleotide biosynthesis, and lack of folate in the diet can lead to anemias caused by inhibition of proliferation of RBC precursors.

Nucleotide Degradation

Nucleotidases and nucleosidases initially participate in purine nucleotide degradation. For example, adenosine is deaminated to produce inosine that, after ribose is removed, generates hypoxanthine, which is used by xanthine oxidase to form uric acid. Immune cells have potent nucleotide salvage pathways, and a lack of adenosine deaminase causes a severe combined immune deficiency (SCID) syndrome. SCID is associated with a large accumulation of dATP in immune cells, which, through a negative feedback mechanism on ribonucleotide reductase, blocks production of dNTPs and results in a failure to replicate DNA.

FUTURE DIRECTIONS

This short review summarizes the central signaling and metabolic pathways that play a pivotal role in all the processes executed by hematopoietic cellular systems. In normal physiologic conditions, these pathways are regulated and operating to achieve homeostatic cellular functions in healthy individuals. In pathologic conditions, however, dysregulation or failure of these pathways leads to diseases of lymphohematopoietic tissues. To a large extent, the main components and regulatory circuitries of these pathways have been elucidated, but the challenge for the future is to fully integrate them and identify therapeutic targets that will enable the development of effective treatments for these diseases.

CHAPTER 7

PHARMACOGENOMICS AND HEMATOLOGIC DISEASES

Leo Kager and William E. Evans

The fundamental hypothesis pursued in genetics is that heritable genetic variation (i.e., genotypes or haplotypes) translates into inherited phenotypes (e.g., disease risk, drug response). On the basis of this hypothesis, the aim of medical genetics and pharmacogenomics is to understand the myriad associations between individual genotypes and specific phenotypes of disease or drug response, with the ultimate goal of better defining the risk for, or outcome of, diseases and the response to specific medications. Many seminal discoveries in medical genetics were made in the course of investigating hematologic disorders, as exemplified by the fact that the most prevalent monogenic disorders, the hemoglobinopathies, affect approximately 7% of the world's population. Pharmacogenomics also has a long tradition in hematology; one of the first documented clinical observations of inherited differences in drug effects was the relationship between hemolysis after antimalarial therapy and the inherited glucose-6-phosphate dehydrogenase activity in erythrocytes.[1]

In the pregenomic era, efforts concentrated on mapping highly penetrant monogenic (Mendelian) loci, for both specific diseases and drug-metabolizing pathways that influence the effects of medications. Since the completion of the first draft of the human genome sequence, genome-wide approaches are being increasingly used to define markers for polygenic loci in complex diseases, identify genetic factors that modify the phenotype of a monogenic disease, and elucidate the interplay of genes encoding proteins involved in multiple pathways of drug metabolism, disposition, and effects.[2] This chapter provides a brief overview of pharmacogenomics, using selected examples to illustrate its impact on the treatment of hematologic diseases.

VARIATION IN THE HUMAN GENOME

The genome-wide systematic identification of heritable (i.e., germline) and acquired (i.e., somatic) variants and the functional analysis of genes, their variants, and related products (i.e., proteins) are revolutionizing the study of disease, the development of new medications, and the optimization of drug therapy. Genomics increasingly enable clinicians to make reliable assessments of a person's risk for acquiring a particular disease, to identify drug targets, and to explain interindividual differences in the effectiveness and toxicity of medications.[3]

The Human Genome Project and subsequent projects such as the International HapMap Project and the 1000 Genomes Project have unveiled many types of variations within the 3 billion base pairs of the human haploid genome (Table 7-1); the spectrum ranges from single–base-pair differences to large chromosome events. Variations encompass single-nucleotide polymorphisms (SNPs) and structural variants (SVs, or genomic rearrangements that affect >50 bp of sequence). Comparisons among human genomes showed that they differ more as a consequence of structural variation than as a result of single nucleotide variation. For practical purposes, the term *sequence variation* is mainly used herein. *Polymorphisms* are defined as common variations in the DNA sequence, that is, typically, although somewhat arbitrarily, as the least common allele having a frequency of 1% or more in the population.

SINGLE-NUCLEOTIDE POLYMORPHISMS

The most common and important inherited sequence variations are SNPs, positions in the genome where individuals have inherited a different nucleotide, and it is now estimated that several million SNPs exist in humans. Many efforts are under way to catalog these variants, because a comprehensive SNP catalog offers the possibility to pinpoint important variants in which nucleotide changes alter the function or expression of a gene that influences diseases or response to pharmacologic treatment. The main public database is dbSNP, and the increase in the number of SNPs (currently about 20 million) is driven largely by the International HapMap Project and the 1000 Genomes Project (see Table 7-1).[3]

SINGLE-NUCLEOTIDE POLYMORPHISMS AND PHENOTYPES

SNPs are present in exons, introns, promoters, enhancers, and intergenic regions. To elucidate the relationship between SNPs and phenotypes of interest, initial efforts have concentrated mainly on SNPs that are likely to alter the function or expression of a gene. However, only a small portion of the identified SNPs lie within coding regions, and only about half of those SNPs cause amino acid changes in expressed proteins. SNPs that cause amino acid changes are referred to as *nonsynonymous SNPs* (nsSNPs). nsSNPs are the main sequence variants underlying most of the highly penetrant inherited monogenic diseases currently known, such as hemoglobinopathies. The likelihood that an nsSNP will result in disease or functional change in drug metabolism depends on the localization and nature of the amino acid change within the encoded protein; software algorithms have been developed to "predict" whether a certain amino acid change is likely to have a major or minor effect on protein function.

Although it is intuitively obvious that amino acid substitutions have the potential to change the function of a protein, gene expression also can be affected by SNPs positioned in regulatory sequences or intronic regions. For example, a "silent" or synonymous SNP has been identified that affects protein folding and function of an important drug transporter, namely ATP-binding cassette transporter ABCB1 (or P-glycoprotein), and this variant has the potential to influence the pharmacology of drugs that are substrates for P-glycoprotein.[4]

As the knowledge of the topology of the genome has evolved, a new class of noncoding RNAs has emerged called micro-RNAs (miRNAs). miRNAs are small (19- to 22-nucleotide-long), single-stranded RNA molecules that can influence cellular mRNA levels or impair translation after binding to miRNA binding sites at the target gene's 3′ untranslated region. SNPs in miRNA binding sites have the potential to alter binding and function of miRNAs. Indeed, a so-called miRSNP, which is defined as a functional SNP that can interfere with micro-RNA (miRNA) function, had been identified to affect the expression of the antifolate target dihydrofolate reductase (DHFR), thereby influencing antifolate pharmacodynamics.[5]

Collectively, these examples demonstrate that SNPs in functionally different genomic regions can influence drug disposition and response.

HAPLOTYPES, LINKAGE DISEQUILIBRIUM, AND HAPMAP

Combinations of SNPs are commonly inherited together in the same region of DNA, forming haplotypes. Genome-wide haplotypes can be constructed by linkage disequilibrium (LD) analysis. LD analysis is a statistical measure of the extent to which particular alleles or SNPs at two loci are associated with each other in the population, and LD occurs when haplotype combinations of alleles or SNPs at different loci occur more frequently than would be expected from random association. SNPs and alleles of interest are presumably inherited together if they are physically close to each other (usually <50 kilobases [kb]), producing strong LD. Therefore SNPs that are in LD with a disease phenotype or response-to-drug phenotype can *mark* the position on the chromosome where a susceptibility gene is located, even though the SNP itself may not be the cause of the phenotype.

By studying millions of SNPs in hundreds of individuals from geographically diverse populations, the international HapMap consortium created genome-wide maps of haplotypes. The HapMap project has revealed a block-like structure of LD, as well as the existence of areas of low or high recombination rate, and this has helped to identify so-called tagging (tag) SNPs. Such tag SNPs can be used to predict with high probability the alleles at other co-segregating "tagged" SNPs, and the number of identified tag SNPs considerably varies among ethnic groups. Of note, recent investigations have demonstrated that common SNPs are also in LD with other common variants in the human genome (i.e., structural variants).[3]

STRUCTURAL GENOMIC VARIANTS

Along with point mutations, SVs have been identified to be the primary sources of variation in the human genome; SVs include insertions, deletions, inversions, mobile element transpositions, duplications, and translocations of DNA segments that are >50 bp or larger. Unbalanced SVs that change the number of base pairs in comparison with a reference genome are defined as copy number variants (CNVs).[6] Many efforts focus on the identification, validation, and mapping of these variants, and the Database of Genomic Variants (dbVAR) currently contains data on more than 66,000 CNVs, 950 inversions, and 34,000 InDels (insertions and deletions; 100 bp to 1 kb) (see Table 7-1). CNVs are found in a wide spectrum of genomic regions; therefore many pharmacologically relevant genes can be affected by these variants. Indeed, CNVs have been described to influence activity of some of the most important drug-metabolizing enzymes, such as cytochrome P450 enzymes and glutathione S-transferases.

SOMATIC GENOMIC VARIANTS

Genomic instability is a "hallmark of cancer cells." Nonrandom genetic abnormalities, including aneuploidy (gains and losses of whole chromosomes) and structural rearrangements that often result in the expression of chimeric fusion genes (e.g., ETV6-RUNX1, BCR-ABL), can be found in the majority of hematologic malignancies. These acquired (somatic) genomic variations can differ significantly from inherited (germline) genomic variations and can, for example, create allele-specific copy number differences between normal host cells and cancer cells. Such differences can have pharmacologically relevant consequences. Indeed, it was shown that the cellular acquisition of additional chromosomes in leukemia cells—for example, the gain of additional chromosomes 21 in hyperdiploid acute lymphoblastic leukemia (ALL) (ALL blast cells with more than 50 chromosomes)—can cause discordance between germline genotypes and leukemia cell phenotypes, which are important when these discordant genotypes/phenotypes influence the disposition of antileukemic agents.[7] Moreover, somatic deletions of genes encoding proteins that regulate the stability of the DNA mismatch repair enzyme MSH2 have been identified in approximately 11% of children with newly diagnosed ALL. These deletions in ALL cells have been shown to cause DNA mismatch repair deficiency and increased resistance to thiopurines, representing a novel genomic mechanism by which leukemia cells can acquire MSH2 deficiency with numerous downstream consequences.[8]

CATALOGUES OF GENOMIC VARIANTS, GENOTYPING PLATFORMS, AND GENOME-WIDE ASSOCIATION STUDIES

Cataloguing the pattern of genome variation in diverse populations is fundamental in understanding areas of human phenotypic diversity such as interindividual and interethnic differences in drug responses; increasingly detailed maps of human genomic variation are provided in public databases (see Table 7-1). Information from these maps has been used to design high-throughput genotyping platforms (e.g., SNP chips that can now assay up to 2 million variants simultaneously), thereby providing tools to interrogate the relationship between genetic variation across the human genome and important phenotypes such as disease or response to medications in a relatively unbiased (agnostic) fashion.[3] Current SNP catalogues encompass roughly up to 95% of variants that are found in at least 10% of humans, and these catalogues have been used in genome-wide association studies to pinpoint genes important to diseases and drug responses.

GENETIC VARIATIONS INFLUENCING DRUG RESPONSE: PHARMACOGENETICS–PHARMACOGENOMICS

Until relatively recently, genetics has played little or no role in finding the right drug and the optimal dosage for individual patients. Mostly empiric approaches are used to select drug therapy, despite the fact that there is great heterogeneity in the way people respond to medications, in terms of both host toxicity and treatment efficacy. Unfortunately, for almost all medications, interindividual differences are the rule, not the exception, and these differences result from the interplay of many variables, including genetics and environment. Variables influencing drug response include pathogenesis and severity of the underlying disease being treated; drug interactions; the patient's age (i.e., developmental pharmacology), sex, nutritional status, and renal and liver function; presence of concomitant illnesses; and other medications. In addition to these clinical variables, increasing evidence points to a substantial inherited component of interindividual differences in drug response. Clinical observations of inherited differences in drug effects (based on family studies and twin studies) were first documented in the 1950s, and the concept of pharmacogenetics was defined initially in 1959 by Friedrich Vogel as "the study of the role of genetics in drug response." The number of recognized clinically important pharmacogenetic traits grew steadily in the 1970s; the elucidation of the molecular genetics underlying these traits began in the late 1980s and 1990s, and their translation to molecular diagnostics is well under way in the 2000s. Of interest, during the last 2 decades, the field of pharmacogenetics was rediscovered by the pharmaceutical industry and by a broader spectrum of researchers in academia. This rediscovery has been driven in large part by the Human Genome Project, and by the recognition that inheritance can play a major role in determining drug effects. The study of pharmacogenetics began with the analysis of genetic variations in drug-metabolizing enzymes and how those variations translate into inherited differences in drug effects. More recently, the field has incorporated genome-wide approaches to identify networks of genes that govern the clinical response to drug therapy (i.e., pharmacogenomics). The terms *pharmacogenetics* and *pharmacogenomics*, however, are synonymous for all practical purposes.

Overall, pharmacogenomics can be viewed as a broad strategy to establish pharmacologic models by integrating information from functional genomics, high-throughput molecular analyses, and pharmacodynamics. Approaches to establish pharmacogenomic models include candidate gene analyses (which focus on the analysis of single genes or sets of functionally related genes in pathways) and genome-wide analyses. Pharmacogenomic models can be used to maximize efficacy and reduce toxicity of existing medications, as well as to identify novel therapeutic targets.

Recent comprehensive reviews on pharmacogenomics are available elsewhere.[1,2,7,9-12] Herein, clinically relevant examples are provided to illustrate how pharmacogenomics can be used to improve current drug therapy for hematologic disorders, to prevent hematologic toxicity, and to identify novel targets for developing new therapeutic approaches in hematology.

OPTIMIZATION OF DRUG THERAPY

Most drug effects are determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications. Pharmacokinetics is the study of the absorption, distribution, metabolism, and excretion (ADME) of drugs. Pharmacodynamics is the relationship between the pharmacokinetic properties of drugs and their pharmacologic effects, either desired or adverse. The ultimate goal of pharmacogenomics in this context is to elucidate the inherited determinants for drug disposition and response to select medications and dosages on the basis of each patient's inherited ability to metabolize, eliminate, and respond to specific drugs. A model of how polygenic variables can determine drug response is illustrated in Fig. 7-1.

GENETIC VARIATIONS THAT INFLUENCE DRUG DISPOSITION

Drug Metabolism

Metabolism often involves reactions that make lipophilic drugs more water soluble and thus more easily excreted. Pathways of drug metabolism are classified as either phase I reactions (which catalyze changes of functional moieties by oxidation, reduction, or hydrolysis) or phase II conjugation reactions (which conjugate functional moieties by acetylation, glucuronidation, sulfation, or methylation). The process of metabolic reactions that inactivate drugs or prodrugs is referred to as *catabolism*. Drug metabolism also includes reactions that convert prodrugs into therapeutically active compounds; these processes are referred to as *anabolism*. Additionally, metabolic reactions can form toxic metabolites.

Essentially all genes encoding drug-metabolizing enzymes (there are more than 30 families of enzymes in humans) exhibit genetic variations, many of which translate into functional changes in the proteins encoded. Inheritance of genes containing sequence variations that alter the function of enzymes encoded or CNVs that alter the expression of functionally relevant genes can influence drug disposition and ultimately determine drug effects (either desired or adverse), if those enzymes are involved in crucial pathways of elimination or activation of the administered medication. Numerous variant enzymes have been characterized; the focus here is on two extensively investigated examples: thiopurine S-methyltransferase (TPMT) and cytochrome P450 (CYP) enzymes.

Thiopurine S-Methyltransferase and Thiopurines

The genetic sequence variation of TPMT provides one of the best and most thoroughly studied examples of a clinically important pharmacogenetic trait. Studies have established that variations within the TPMT gene locus are a major determinant of the effects of thiopurines, which are widely prescribed structural analogs of purines. The prodrugs mercaptopurine (MP) and thioguanine are among the agents that constitute the "backbone" of treatment for childhood ALL.

The hydrophilic thiopurines are transported into target cells, where they undergo extensive metabolism. Metabolic reactions include anabolism (via a series of enzymes, the first of which is hypoxanthine phosphoribosyltransferase) to form active cytotoxic thioguanine nucleotides (TGNs) and catabolism, including phase I (oxidation via xanthine oxidase) and phase II (S-methylation via TPMT) reactions. In hematopoietic cells such as leukemic blasts, xanthine oxidase is low or absent; therefore degradation via TPMT is essentially the only path by which thiopurines can be inactivated. TPMT activity determines how much of these intracellular prodrugs are inactivated to methylated metabolites and how much remains available for activation to TGNs. TGNs are responsible for the efficacy in leukemic blasts and toxicity in normal hematopoietic tissues.[13]

TPMT activity is inherited as an autosomal codominant trait. Approximately 90% to 95% of persons are homozygous for the wild-type (wt) allele (TPMT*1) and have "normal" enzyme activity; approximately 5% to 10% are heterozygous for the polymorphism and have intermediate levels of enzyme activity; 1 in 300 persons inherit two variant (nonfunctional) TPMT alleles that cause TPMT deficiency. TPMT activity typically is measured in erythrocytes, because this measure correlates with the activity in other normal and neoplastic tissues.[13]

Three nsSNPs account for more than 95% of the clinically relevant TPMT variant alleles, namely, TPMT*2 (238G>C, rs1800462), TPMT*3C (719A>G, rs1800460), and TPMT*3A (contains two nsSNPs: 460G>A, rs1142345; and 719A>G, rs1800460). Other TPMT variants are very rare. These sequence variants of TPMT do not affect its messenger RNA (mRNA) expression; rather, they render the variant protein more susceptible to

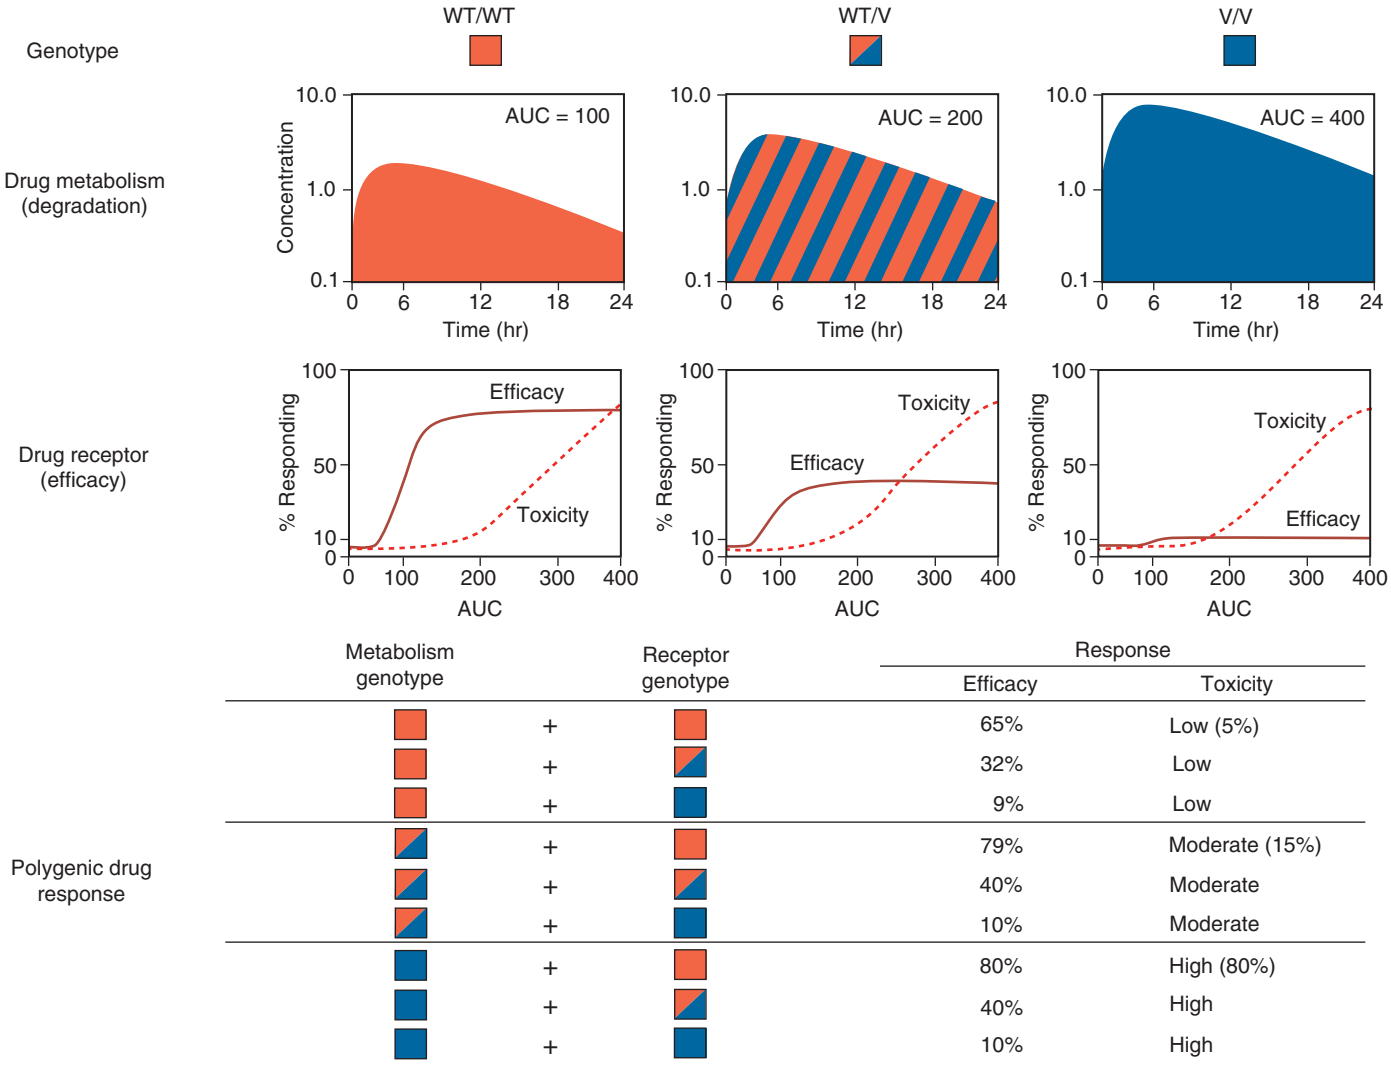

Figure 7-1 POLYGENIC DETERMINANTS OF DRUG RESPONSE. The potential effects of two genetic variants are illustrated. One genetic variant involves a drug-metabolizing enzyme *(top)*, and the second involves a drug receptor *(middle)*. Differences in drug clearance (or the area under the plasma concentration–time curve [AUC]) and receptor sensitivity are depicted in patients who are either homozygous for the wild-type allele *(WT/WT)* or heterozygous for one wild-type and one variant *(V)* allele *(WT/V)*, or have two variant alleles *(V/V)* for the two genetic variants. At the *bottom* are shown the nine potential combinations of drug metabolism, drug-receptor genotypes, and the corresponding drug-response phenotypes, which were calculated with data from the top. The therapeutic indexes (efficacy-to-toxicity ratios) ranged from 13 (65%:5%) to 0.125 (10%:80%). *(Modified with permission from Evans WE, McLeod HL: Pharmacogenomics: Drug disposition, drug targets, and side effects.* N Engl J Med *348:538, 2003. Copyright 2003 Massachusetts Medical Society. All rights reserved.)*

proteasome-mediated degradation, and persons inheriting these alleles have a low (in heterozygotes) or undetectable (in the *variant*/*variant* genotype) level of TPMT activity. Subsequent studies demonstrated that the TPMT*3A variant disrupts the structure of the encoded enzyme, resulting in misfolding, protein aggregation (so-called aggresome formation) and rapid degradation of TPMT monomers and aggregates. The prevalence of TPMT allelic variants differs among ethnic populations. TPMT*3A is the most common variant in Caucasians, and TPMT*3C is the predominant variant in Asians and Africans.[13]

Childhood ALL studies have shown that essentially all homozygous TPMT-deficient patients experience dose-limiting hematotoxicity, and some experience life-threatening hematotoxicity if given conventional doses of thiopurines. Patients with only one nonfunctional TPMT allele have intermediate tolerance to thioguanine therapy. Although many patients with only one nonfunctional TPMT allele can tolerate thiopurine therapy at essentially full doses, they are at higher risk for dose-limiting hematotoxicity than are those patients who have a wild-type TPMT genotype (e.g., 35% cumulative risk versus 7% cumulative risk in a study of ALL patients).[7]

In TPMT-deficient patients, the thiopurine dose must be reduced to 10% to 15% of the conventional doses (i.e., an 85% to 90% dose reduction of the conventional 75 mg/m^2/day MP dose) to avoid severe hematopoietic toxicity. At these very low thiopurine doses, TPMT-deficient patients have erythrocyte TGN levels that are comparable to (or greater than) those of "wild-type patients" given full doses. Although many patients with one nonfunctional TPMT allele can tolerate essentially full doses of thiopurines (dependent on starting dose and other therapy), thiopurine-intolerant heterozygous patients typically require a 50% dose reduction. Multivariate analyses have demonstrated that children who have ALL and at least one *TPMT*-variant allele tend to respond well to MP therapy (i.e., 75 mg/m^2/day) and may experience better leukemia control than is obtained in those who have two wild-type TPMT alleles. However, it was observed in the same patient group (St. Jude Children's Research Hospital Total protocols) that those who are treated with thiopurines and have deficient TPMT activity (i.e., all patients except those with a *1/*1 genotype) are at an increased risk for epipodophyllotoxin-related acute myeloid leukemia (therapy-related AML, or t-AML) or irradiation-induced brain tumors.[7] Similar results (with similar MP

doses) have been reported from the Scandinavian Nordic Society of Pediatric Haematology and Oncology (NOPHO) ALL-92 trial, with a significantly higher risk for t-AML or myelodysplastic syndrome in patients with lower TPMT activity compared with control patients. Of note, in children treated on Berlin–Frankfurt–Muenster (BFM) protocols with lower starting doses of MP in continuation therapy (i.e., 50 mg/m^2/day versus 75 mg/m^2/day) and lower doses of MP in combination with high-dose methotrexate infusions (i.e., 25 mg/m^2/day versus 75 mg/m^2/day), TPMT genotype was not associated with a higher risk for secondary malignant disease.

On the other hand, another study from the BFM ALL group raised the question whether dose escalation in patients with wild-type TPMT would yield greater efficacy in protocols that routinely use lower MP doses (i.e., 50 to 60 mg/m^2/day). In this investigation, the TPMT genotype was linked to early ALL treatment response, which was determined by measuring minimal residual disease after induction and consolidation treatment that included a 4-week cycle of MP 60 mg/m^2/day. Children with the *1/*1 genotype were found to have a 2.9-fold higher risk for positive minimal residual disease than did TPMT-heterozygous patients. In contrast to TPMT-heterozygous patients treated at St. Jude Children's Research Hospital (who received more prolonged MP treatment with modestly higher MP doses of 75 mg/m^2/day), for whom the risk for dose-limiting hematopoietic toxicity is increased, TPMT-heterozygous patients treated with lower MP doses according to BFM protocols did not have higher toxicity compared with TPMT wild-type patients. Furthermore, in the St. Jude Total protocols, prospective MP dose adjustments (i.e., reduced doses in heterozygotes) were associated with less toxicity without compromise in treatment efficacy.[7]

Of note, in children treated with combination chemotherapy for ALL in whom MP dose was adjusted according to TPMT genotypes, a sequence variant in inosine triphosphate pyrophosphatase (ITPA, another enzyme involved in purine metabolism) was identified as a significant determinant of MP metabolism and of severe febrile neutropenia, illustrating that when treatment is adjusted for the most penetrant (strongest) genetic polymorphism, less penetrant polymorphisms can emerge as clinically important.[14]

More than 98% concordance exists between TPMT genotype and phenotype, and genotyping is very reliable (90% sensitivity, 99% specificity) in identifying patients who have inherited one or two nonfunctional alleles. In 2004 the U.S. Food and Drug Administration (FDA) prompted additions to the label for MP providing TPMT testing and dosage recommendations for TPMT-deficient patients. Evidence suggests that TPMT genotyping before initiation of MP treatment can be cost effective in children with ALL. By using the TPMT genotype to individualize thiopurine therapy, clinicians can now diagnose inherited differences in drug response, thereby preventing serious toxicities. Guidelines for TPMT genotype and thiopurine dosing are available from the Clinical Pharmacogenetics Implementation Consortium (CPIC); these guidelines are periodically updated at the Pharmacogenomics Knowledge Base (PharmGKB)[15] (also see Table 7-1, box on Relevance to Clinical Hematology, and Fig. 7-2).

Relevance to Clinical Hematology

Mercaptopurine Dosage Adjustment Based on TPMT Genotypes in Acute Lymphoblastic Leukemia

Mercaptopurine (MP) is a mainstay of treatment of childhood acute lymphoblastic leukemia (ALL). However, conventional doses of this prodrug can induce severe hematotoxicity in patients who have impaired thiopurine metabolism in hematopoietic tissues owing to less-stable thiopurine S-methyltransferase (TPMT) enzyme variants. The three major variant alleles (TPMT*2, TPMT*3C, and TPMT*3A) encoding the variant proteins can quickly be determined by commercially available Clinical Laboratories Improvement Act–certified molecular diagnostics or in special laboratories (e.g., Prometheus Labs, San Diego, Calif) using samples obtained from peripheral blood before MP therapy. In patients with two nonfunctional alleles (1 out of 300), MP dosage must be reduced to 10% to 15% of conventional 75 mg/m^2/day dosages. Patients with one variant allele (5% to 10% of the population) can tolerate MP at full dosage; however, in intolerant patients, a dose reduction of 50% often is required.[15] For more details, refer to this chapter's text discussion.

Cytochrome P450 Enzymes

The cytochrome P450 (CYP) superfamily is a system of phase I enzymes involved in the metabolism of endogenous substances (e.g., steroids, arachidonic acid, vitamin D_3) and exogenous compounds (e.g., drugs, environmental chemicals, pollutants). In humans, the CYP enzymes are encoded by more than 57 genes, and the majority of genes are polymorphic. Updated information regarding the nomenclature and properties of the variant alleles with links to the dbSNP database is available at the human CYP allele Web site (see Table 7-1). On the basis of the composition of CYP variant alleles, individuals have been categorized into four major phenotypes: poor metabolizers (PM, having two loss-of-function alleles), intermediate metabolizers (IM, being deficient in one allele), extensive metabolizers (EM, having two copies of functional alleles), and ultrarapid metabolizers (UM, having three or more functional gene copies, or two increased-activity alleles, or one functional allele plus one increased activity allele).

Different populations of metabolizers have been linked to variants in the coding region of CYP genes, SNPs in intronic regions, which alter CYP gene mRNA expression, CNVs (e.g., gene deletions, gene duplications) of CYP genes, or differences in the methylation at CpG islands in promoter and 5′ regions, which alter expression of CYP genes.[16]

Many pharmacologically relevant variants in CYP genes have been identified. The focus here is on the variants in CYP2C9 and CYP2C19. These CYP enzymes strongly influence the metabolism of two extensively prescribed medications: warfarin and clopidogrel.

CYP2C19 and Clopidogrel

Platelets play a crucial role in thrombosis and the development of acute coronary syndromes (ACS) because a platelet-rich thrombus forms at the site of the ruptured atherosclerotic plaque. Thus inhibition of platelet function is an effective strategy in the treatment and prevention of thrombosis of arteriosclerotic origin, especially after percutaneous coronary interventions (PCI). Main classes of antiplatelet agents for clinical use include aspirin, the thienopyridines (clopidogrel and prasugrel), the nonthienopyridine $P2Y_{12}$ receptor antagonists (ticagrelor), and intravenous GPIIb/IIIa antagonists.

Clopidogrel is an orally administered antiplatelet prodrug, and dual antiplatelet treatment with aspirin and clopidogrel is currently (2011) the guideline-approved standard of care in patients with ACS and PCI with stenting. According to the American Heart Association, approximately 470,000 persons in the United States will have a recurrent heart attack annually; therefore it is not surprising that clopidogrel was reported to be amongst the best-selling drugs in the world in 2009. However, about 20% of patients have been reported to be "resistant" to clopidogrel treatment.

Intestinal absorption of clopidogrel is diminished via the P-glycoprotein transporter (encoded by the polymorphic ABCB1 gene); once absorbed, 85% of clopidogrel is inactivated via esterases, and only about 15% of the prodrug is available for the two-step activation via hepatic CYP enzymes. The active drug selectively and irreversibly binds to the ADP-dependent $P2Y_{12}$ receptor on thrombocytes and thereby inhibits platelet activation and aggregation for the platelets' life span, which is about 10 days.

Candidate gene investigations identified a "high-risk" pharmacokinetic profile for clopidogrel, and functional variants in the drug

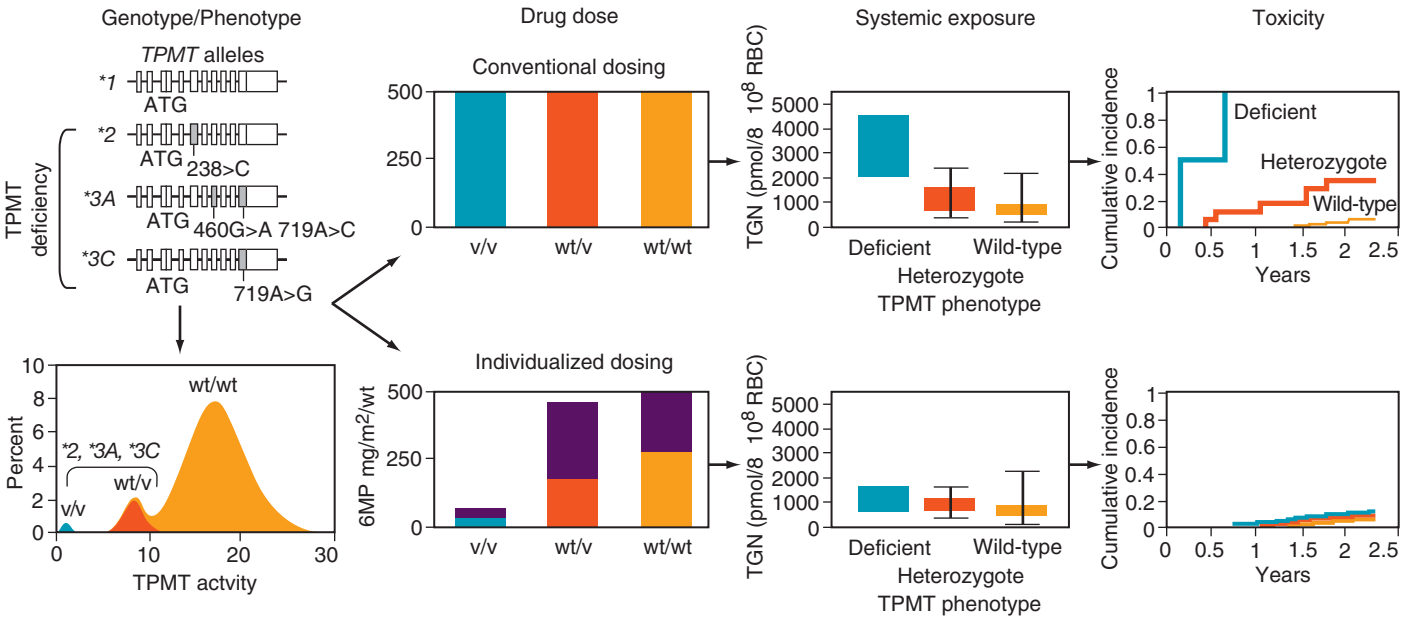

Figure 7-2 Genetic polymorphism of thiopurine methyltransferase (TMPT) and its role in determining toxicity to thiopurine medications. Under "Genotype/Phenotype" *(far left)* are depicted the predominant *TPMT* mutant alleles that cause autosomal codominant inheritance of TPMT activity in humans. As shown in the graphs under "Drug Dose," "Systemic Exposure," and "Toxicity," when uniform (conventional) dosages of thiopurine medications (e.g., azathioprine, mercaptopurine [6MP], thioguanine) are administered to all patients, TPMT-deficient patients accumulate markedly higher (10-fold) cellular concentrations of the active thioguanine nucleotides (TGN), and TPMT-heterozygous patients accumulate approximately twofold higher TGN concentrations, which translate into a significantly higher frequency of toxicity *(far right)*. As depicted in the bottom row of graphs, when genotype-specific dosages of thiopurines are administered, comparable cellular TGN concentrations are achieved, and all three TPMT phenotypes can be treated without acute toxicity. In the two graphs under "Drug Dose," the *solid* or *striped* portion of each bar depicts the mean 6MP doses that were tolerated in patients who presented with hematopoietic toxicity; the *stippled* portion depicts the mean dosage tolerated by all patients in each genotype group, not just those patients presenting with toxicity. *v,* Variant; *wt,* wild-type. *(Reproduced with permission from Evans WE: Thiopurine S-methyltransferase: A genetic polymorphism that affects a small number of drugs in a big way.* Pharmacogenetics *12:421, 2002.)*

activating cytochrome P450 enzyme CYP2C19 were shown to significantly affect drug response.[12] In a recent metaanalysis that included almost 10,000 patients, a significantly higher risk for adverse cardiovascular events was found in individuals who had reduced-function variants of CYP2C19, because these patients cannot activate the parent drug to its active metabolites, as well as patients with the wild-type CYP2C19 genotype.[17] The most important poor metabolizer alleles in CYP2C19 are *2 (681G>A, rs 4244285, ≈15% in Caucasians and Africans, ≈30% in Asians) and the less frequent *3 (636G>A, rs 4986893, 2% to 9% in Asians, less than1% in Caucasians and Africans). Other CYP2C12 variant alleles (*4 to *8) that encode enzymes with low or absent activity are very rare, with allele frequencies of less than 1%.[18]

On the other hand, the CYP2C19*17 gain-of-function allele (806C>T, rs12248560, multiethnic allele frequencies from 3% to 21%) results in enhanced CYP2C19 enzyme activity and can place these ultra-metabolizing individuals at a higher risk for bleeding because of increased drug activation.[18]

In a small study including 40 patients, increased doses of clopidogrel in PM patients resulted in better antiplatelet response. However, the first large randomized controlled trial addressing this important issue was not able to confirm this, and a metaanalysis and systematic review in 2011 did not find a consistent influence of CYP2C19 genotypes on clinical efficacy of clopidogrel.[9,12,19] Potential reasons for these negative trials have been reviewed, including differences among patient groups (e.g., differences in the percentage of patients who had undergone PCIs) and differences in study designs.[9,10,12,18]

The FDA has issued a "black box" warning for clopidogrel in regard to reduced effectiveness in PM individuals carrying two defective CYP2C19 alleles, and genotyping for the important variants is widely available in the United States. Further prospective trials are underway to clarify whether clopidogrel dosing based on genetic biomarkers is clinically useful. The CPIC has recently published guidelines for CYP2C19 genotype-directed antiplatelet therapy; these guidelines are periodically updated at the Web site of the PharmGKB (see Table 7-1).[18]

Other strategies to overcome the drug resistance mechanism of clopidogrel (i.e., low functional variants of CYP2C19) focus on bypassing of the "high-risk" pharmacokinetic pathway. The third-generation thienopyridine prasugel, for example, is mainly metabolized by the less polymorphic CYP3A4 enzyme. The pharmacokinetics of the nonthienopyridine $P2Y_{12}$ inhibitor ticagrelor are not affected by CYP2C19 variants.[9,12]

CYP2C9, VKORC1, and Warfarin

In the United States, the oral vitamin K antagonist warfarin is widely used to prevent thromboembolic events in patients with chronic conditions such as atrial fibrillation, and the drug is prescribed to more than 1 million persons annually. A narrow therapeutic index with a risk for serious hemorrhage and interindividual variability in response to warfarin necessitate individualization of treatment, which has been based primarily on monitoring prothrombin time via the international normalized ratio (INR) testing.

Several candidate gene studies have demonstrated that CYP2C9 genotype influences warfarin anticoagulant dose requirements and bleeding risks. CYP2C9 is the principal CYP2C isoenzyme in the human liver, and it is involved in the oxidative metabolism of several clinically important drugs, including oral anticoagulants, phenytoin, and various nonsteroidal antiinflammatory drugs.[16]

To date, numerous polymorphic alleles (CYP2C9*1 to *35) have been identified for the known CYP2C9 gene, at least half of which are associated with diminished enzyme activity in vitro. The two most common CYP2C9 variants are CYP2C9*2 (430C>T; rs1799853, Arg144Cys) and CYP2C9*3 (1075A>C; rs1057910, Ile359Leu).

Approximately 35% of Caucasians have one or two of these variant alleles; the overall allelic frequency of CYP2C9*2 is approximately 10%, and that of CYP2C9*3 is 8%. The *2 and *3 variants are virtually nonexistent in Africans and Asians; 95% of these persons express the wild-type genotype (i.e., extensive metabolizers).

Both CYP2C9*2 and CYP2C9*3 are important in the metabolism of the anticoagulants warfarin, acenocoumarol, and phenprocoumon. The required dose of warfarin is lowest if CYP2C9*3 is present, as predicted by in vitro studies that compared the functional effects of the two variant alleles. In addition, heterozygosity for CYP2C9*2 significantly affects overall CYP2C9 activity. Warfarin is a racemic mixture of R- and S-enantiomers that differ in their patterns of metabolism and in their potency of pharmacodynamic effect. Although S-warfarin exhibits a three- to fivefold higher inhibitory effect on the target enzyme vitamin K epoxide reductase, differences in metabolism result in an approximately twofold higher plasma concentration of R-warfarin. It has therefore been suggested that S-warfarin accounts for 60% to 70% of the overall anticoagulation response and R-warfarin accounts for 30% to 40%.[20]

A number of CYP isoforms contribute to warfarin metabolism; however, 6- and 7-hydroxylation by CYP2C9 is the most important inactivation pathway of S-warfarin. Compared with the amount of S-warfarin metabolized by wild-type enzyme (encoded by the CYP2C9*1 allele), metabolism by the enzyme encoded by the CYP2C9*2 variant is reduced by approximately 30% to 50%, and the amount metabolized by the enzyme encoded by the CYP2C9*3 variant is reduced by 90%. The substantial reduction in turnover seen with the CYP2C9*3 variant may be caused by the amino acid substitution Ile359Leu within the substrate-binding site of the enzyme.

It was well established that *CYP2C9* genotype is correlated with warfarin, acenocoumarol, and phenprocoumon metabolism and dose requirement. However, because interindividual variability in the dose requirement occurred within the various CYP2C9 groups, genotyping for additional polymorphic genes that encode clotting factors, transporters, and warfarin targets was performed.

An important pharmacogenomic finding was the identification of a novel pharmacodynamic mechanism underlying warfarin resistance—the discovery of sequence variants in the warfarin target gene VKORC1, which encodes the vitamin K epoxide reductase complex 1.[20] This complex regenerates reduced vitamin K for another cycle of catalysis, which is essential for the posttranslational γ-carboxylation of vitamin K–dependent clotting factors II (prothrombin), VII, IX, and X (Fig. 7-3). The identification of common variants in VKORC1 has quickly emerged as one of the most important genetic factors determining coumarin dose requirements.

Main VKORC haplotypes include the putative ancestral haplotype VKORC1*1, the haplotype VKORC1*2 (which is more sensitive to warfarin), and the haplotypes VKORC1*3 and *4 (which are more resistant to warfarin). There are major differences in the distribution of VKOCR1 haplotypes among ethnic groups, and this may explain interethnic differences in coumarin requirement. For example, the significantly higher average warfarin requirement in Africans is in line with significantly lower occurrence of the VKORC1*2 haplotype in Africans.

Genome-wide association (GWA) studies in patients treated with warfarin and acenocoumarol showed two major signals in and around VKORC1 and CYP2C9 and identified a much weaker additional association with CYP4F2. These GWA studies indicated that any other genetic factors are of much less importance in determining warfarin dose. CYP2F4 was subsequently identified to catalyze vitamin K oxidation. Overall, the hereditary pharmacodynamic factor VKORC1 explains approximately 25% of the variance in coumarin dose requirement, the hereditary pharmacokinetic factor CYP2C9 explains about 15%, and CYP4F2 explains about 3%.[20]

The FDA has updated the label on warfarin, providing VKORC1 and CYP2C9 genotype-specific ranges of doses and suggesting that VKORC1 and CYP2C9 genotypes be taken into consideration when the drug is prescribed. Additionally, dosing algorithms are available online, including genetic and nongenetic information that can help to optimize warfarin starting dose (see Table 7-1). In comparison with a matched historic control group that started on warfarin treatment without genotyping, 900 patients who were treated with warfarin and for whom CYP2C9 and VKORC1 genotypes were available had a 28% lower risk for being hospitalized for hemorrhage.[9,10,12,20] Before this can become the standard of care, findings of trials currently underway will be important to further confirm the benefit of including safety, cost-effectiveness, and feasibility of individualized dosing regimens that include genomic biomarkers. Alternative anticoagulants are being developed; for example, the dosing of dabigatran, which acts as a direct thrombin inhibitor, is not influenced by these genetic polymorphisms, which makes this drug a potential alternative for patients in whom heredity is associated with extreme variations in warfarin effects.

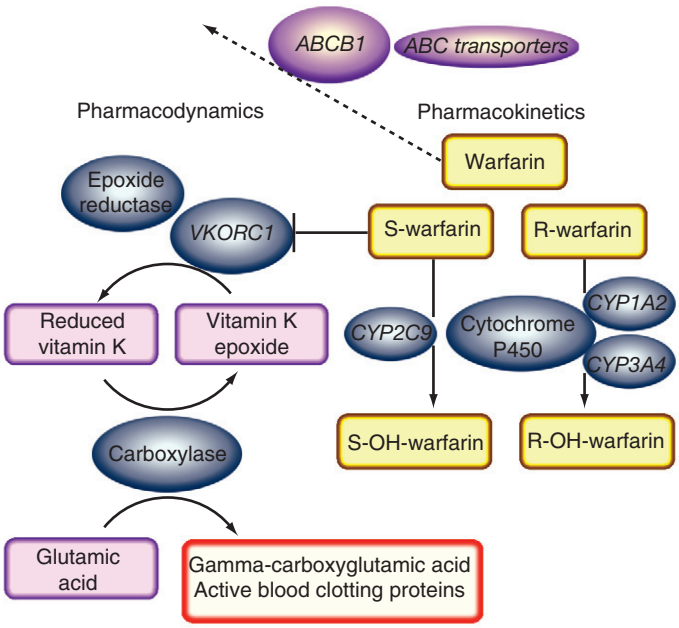

Figure 7-3 The cytochrome P450 isoenzymes CYP2C9 (to a much lesser extent CYP3A4 and CYP1A2) and vitamin K epoxide reductase complex 1 VKORC1 genotypes influence warfarin dose requirement. The racemic mixture of R- and S-warfarin (higher pharmacodynamic effect of S-warfarin) inhibits the reductase in the vitamin K cycle, impairing the synthesis of active vitamin K-dependent clotting factors in liver cells and causes bleeding. R- and S-warfarin are metabolized via hepatic CYP isoenzymes and there is evidence that warfarin is transported out of the liver into the bile via the ATP-dependent transporter (ABC transporter) ABCB1 (or P-glycoprotein).

DRUG TRANSPORTERS

Although passive diffusion accounts for tissue distribution of some drugs and metabolites, an increased emphasis is being placed on the role of membrane transporters. Membrane transporters move drugs and metabolites across the gastrointestinal tract into systemic circulation and across hepatic and renal tissue into the bile and urine for excretion. They also distribute drugs into "therapeutic sanctuaries," such as the brain and testes, and transport them into and out of sites of action, such as leukemic blast cells, cardiovascular tissue, and infectious microorganisms.

Adenosine Triphosphate-Binding Cassette Transporters

The most extensively studied transmembrane transporters are the adenosine triphosphate (ATP)-binding cassette (ABC) family of membrane transporters, which utilize ATP to move substrates across membranes. There are seven subfamilies of ABC transporters, including the P-glycoprotein MDR1, which is encoded by the multidrug-resistance gene 1 (MDR1; i.e., ABCB1), the nine multidrug-resistance proteins (MRP1 to MRP9; i.e., ABCC1 to ABCC9), and other proteins such as breast cancer-resistance protein (BCRP; i.e., ABCG2) and bile salt export protein (BSEP; i.e., ABCB11). The function, substrate specificity, and organ distribution among different transporters vary. For example, a principal function of the P-glycoprotein (MDR1) is the energy-dependent cellular efflux of numerous substrates (e.g., anticancer drugs, immunosuppressive agents, glucocorticoids, antiplatelet drugs, and bilirubin). The expression of MDR1 in many tissues, including the kidney, liver, intestinal tract, and choroid plexus, suggests that this membrane transporter plays an important role in the absorption and distribution of xenobiotics. MDR1 excretes xenobiotics and their metabolites into urine, bile, and the intestinal lumen and transports substances across the blood-brain barrier. Genetic polymorphisms of the ABC transporters are being increasingly investigated in the field of hematology.

For example, individuals who are homozygous for an ABCB1 (putative gain-of-function) coding region variant allele (3435C>T, rs1045642) have been identified as more likely to display failure of efficacy during antiplatelet therapy with clopidogrel, because in these individuals the prodrug may be stronger effluxed into the intestine. Moreover, an SNP in the ABCC4 gene (2269G>A, rs3765534) that strongly reduces the function of the encoded MRP4 protein has been identified, and this ABCC4 variant may be a locus accounting for enhanced thiopurine sensitivity among susceptible populations.

Although transporters such as MDR1 transport various substrates and thus have rather low substrate specificity, other transporters (e.g., the reduced folate carrier SLC19A1) transport only a few specific molecules and their analogs and thus have much higher substrate specificity. Functionally important polymorphisms in transporters with high substrate specificity might be of even greater interest in pharmacogenomics than those with low specificity, because the former can affect the distribution of specific drugs.

Organic Anion-Transporting Polypeptide 1B1 (OAT1B1) and Methotrexate

The solute carrier organic anion-transporter family member 1B1 gene (SLCO1B1), which is localized on chromosome 12, encodes a transporter molecule (OATP1B1) that is located primarily on the sinusoidal face of human hepatocytes. OATP1B1 mediates the hepatic uptake of many endogenous compounds (e.g., bilirubin, bile acids) and xenobiotics such as HMG-CoA reductase inhibitors (e.g., simvastatin), antibiotics (e.g., benzylpenicillin) and cytostatic drugs (e.g., irinotecan) from sinusoidal blood, resulting in their net excretion from blood (likely via biliary excretion).[21]

A common sequence variant in the coding region of SLCO1B1 (521T>C, rs4149056, protein V174A) decreases the transport activity of the encoded protein and results in markedly increased plasma concentrations of drugs that are eliminated from the blood via hepatic uptake. Using genome-wide pharmacogenomic association studies, correlations have been established between variants in SLCO1B1 and myopathy after treatment with the HMG-CoA reductase inhibitor simvastin.[21]

In the field of hematology, a GWA study (interrogating 500,568 germline SNPs) was performed in a discovery cohort of 434 children with ALL in order to identify determinants for MTX clearance, which is important for MTX clinical antileukemic effects and toxicity. Of interest, two SNPs in the SLCO1B1 gene—namely, rs11045879 and rs4149081—were identified to be associated with MTX clearance and gastrointestinal (GI) toxicity. These associations were confirmed in a validation cohort of 206 children. Of note, the rs11045879 and the rs4149081 SNPs were in complete linkage disequilibrium ($r^2 = 1$) with each other and also showed a significant correlation with the 521T>C SNP (rs4149056) ($r^2 > 0.84$), which was not included in the genome-wide genotyping. The rs4149056 was genotyped in a subset of the patients, and the 521C allele was found to be associated with a reduced clearance of MTX at the genome-wide significance level. Of note, no inherited variants in other genes were associated with MTX clearance.[22]

Whereas the mechanisms behind the observed effects remain to be determined, this investigation illustrates how GWA studies can help to identify pharmacologically relevant candidate genes.

GENETIC VARIATIONS INFLUENCING DRUG TARGETS

To exert their pharmacologic effects, most drugs interact with specific target proteins, such as receptors, enzymes, or proteins involved in signal transduction, cell cycle control, or other cellular events. Molecular studies have revealed that many of the genes encoding these drug targets exhibit genetic variations, which can alter the sensitivity of these targets to specific medications (e.g., *VKORC1* and warfarin effects). The following section illustrates this, focusing on somatic genetic variants in hematologic malignancies that alter the targets of tyrosine kinase inhibitors.

BCR-ABL and Tyrosine Kinase Inhibitors

The increased tyrosine kinase activity of the BCR-ABL1 protein—a reciprocal translocation t(9;22)(q34;q11) causes the fusion of the tyrosine kinase ABL1 to BCR, leading to constitutive activation of ABL1—is the driving oncogenic event in the majority of patients with chronic myeloid leukemia (CML) and in a subset of patients with ALL (Ph+ ALL). This realization resulted in the development of specific tyrosine kinase inhibitors (TKI). The treatment of CML was revolutionized at the turn of the century with the introduction of the first TKI imatinib, a small molecular-weight drug that binds to ABL1, thereby leading to inhibition of tyrosine phosphorylation of proteins involved in signal transduction. Imatinib was shown to induce durable remissions in CML patients, which led to a paradigm shift in cancer treatment—that is, a more targeted therapy instead of the nonspecific inhibition of rapidly dividing cells.

Although most patients with CML are expected to have a favorable outcome when treated with imatinib, some patients eventually fail on therapy as a result of acquired point mutations in the target kinase ABL1 that induce drug resistance. More than 100 different mutations with varying degrees of clinical relevance have been identified; for example, encoded variant kinases can block binding of imatinib through steric hindrance or by switching ABL1 into the active form.

Repeated testing for imatinib-resistant variants can have important therapeutic implications in terms of the selection of second-generation TKIs (nilotinib and dasatinib); most variants that confer resistance to imatinib (only a small number account for the majority of resistant cases) retain sensitivity to nilotinib and/or dasatinib. However, one relatively common variant, the T315I or "gatekeeper"

variant, confers resistance to all three drugs by stabilizing the active form of ABL1 to block imatinib and nilotinib binding and introducing a steric clash with dasatinib in the ATP pocket. To overcome these resistance mechanisms of the T315I variant, a "switch-control inhibitor" (DCC-2036) was recently designed that is able to stabilize the BCR-ABL1 T315I variant in the inactive confirmation; phase I clinical trials with this promising drug are underway.[23] In addition, novel TKIs such as ponatinib (which specifically target the T315I gatekeeper mutation) are already entering advanced clinical development stages.

Upfront and repeated monitoring of the mutational status in patients with BCR-ABL1–positive leukemias can help select appropriate TKIs and tailor TKI treatment and also has the potential to provide valuable information on mechanisms underlying selection of resistant clones during TKI therapy.

C-KIT and Tyrosine Kinase Inhibitors

Imatinib and other TKIs do not just target the ATP-folding site of BCR-ABL1; they also inhibit kinases, including C-KIT, platelet-derived growth factor receptor (PDGFR), and others. The C-KIT proto-oncogene encodes the type III transmembrane receptor tyrosine kinase (RTK), which plays an important role in the development of stem cells in the bone marrow and other tissues. C-KIT is expressed in hematopoietic progenitor cells, mast cells, interstitial cells in the gastrointestinal tract, melanocytes, germ cells, and in a subset of cerebellar neurons. Upon binding the dimeric C-KIT ligand, stem cell factor (SCF), C-KIT undergoes dimerization and autophosphorylation, resulting in consecutive activation of the intrinsic C-KIT tyrosine kinase. C-KIT activates multiple downstream signal transduction pathways (e.g., phosphatidylinositol-3-kinase/AKT and Janus-activated kinase [JAK]/signal transducer and activator of transcription [STAT] pathways) and thus has an important role in cell proliferation, self-renewal, differentiation, and other processes.

Gain-of-function mutations in c-KIT can be found in numerous human cancers. For example, up to 70% of gastrointestinal stromal tumors (GISTs) harbor a mutation in the juxtamembrane domain (exon 11) of c-KIT, and this variant is more responsive to imatinib treatment. In aggressive systemic mastocytosis (ASM), a disease with clonal neoplastic proliferation of mast cells that infiltrate hematopoietic (and other) tissues, about 90% of affected individuals have the activating c-KIT 2447A>T, resulting in the C-KIT D816V variant. The activation c-KIT mutation D816V seems to lead to conformational changes in the KIT molecule, which block binding of imatinib and result in resistance to imatinib.[24]

The examples of TKIs and variants in their targets (e.g., BCR-ABL, c-KIT, PDGFR) provide clear evidence that the use of genetic biomarkers can help select drugs and tailor therapy. This has also been recognized by regulatory authorities; for example, the FDA approved imatinib only for adults with ASM without D816V c-KIT mutations or with unknown c-KIT mutational status.

ADVERSE DRUG EFFECTS PRESENTING AS HEMATOLOGIC DISORDERS

Adverse drug reactions (ADRs) constitute a major clinical problem, and strong evidence indicates that ADRs account for approximately 5% of all hospital admissions and increase the length of hospitalization by 2 days. Although the factors that determine susceptibility to ADRs are unclear in most cases, there is increasing interest in the role of genetics; therefore the availability of a genetic test that identifies patients at risk for rare but serious adverse effects has particular appeal. Based on the clinical relevance of ADRs, the FDA has provided advice on the use of certain biomarkers (e.g., variants in TPMT, UGT1A1, CYP2C19) to avoid serious adverse drug effects; a full list of these biomarkers is available at the FDA Web site (see Table 7-1). This list includes, for example, a dosage and administration warning label for irinotecan to prevent severe hematotoxicity based on the assessment of sequence variants in the uridine diphosphate glucuronosyltransferase (UGT) 1A1 gene (i.e., a reduction in the starting dose is recommended for patients homozygous for UGT1A1*28 allele).[10,11] Several medications whose adverse effects have been associated with variability in candidate genes and manifest predominantly as hematologic abnormalities are listed in Table 7-2.

DRUG DEVELOPMENT

Optimizing the selection and dosage of medications is a principal goal of pharmacogenomics. Another important application is in drug development, which is evolving in parallel with improved insights into the mechanisms by which medications exert their pharmacologic effects. Such improved insights into the mechanism(s) of drug action in target cells can help elucidate mechanisms that confer drug resistance, and they will facilitate the development of strategies to further enhance efficacy. This knowledge can be used as a basis to engineer drugs that amplify treatment effects or bypass resistance mechanisms, or both.

Here we focus on examples to show how insights from pharmacogenomic investigations have helped to develop novel strategies to further improve outcome in subgroups of children with ALL who still have a poor outcome despite intensive treatment with current multiagent risk-adapted therapies (so-called high-risk ALL, or HR-ALL). Although excellent outcomes with 5-year event-free survival of higher than 80% can be achieved in childhood ALL in industrial countries, ALL is still a leading cause of death from disease in children older than 1 year of age, and treatment of children with HR-ALL remains one of the greatest challenges in pediatric oncology. HR-ALL features include the resistance of leukemia cells to steroids (i.e., poor steroid responders in BFM-based treatment trials) and multidrug therapy (clearance of leukemia blasts in the peripheral blood, bone marrow, and sanctuary sites), and the presence of certain genetic alterations in leukemia cells—for instance, mixed-lineage leukemia (MLL)–rearrangements (especially in infants), the BCR-ABL1 fusion gene (Ph+ ALL), and (recently identified) alterations in the IKZF1 gene, which is encoding the early lymphoid transcription factor IKAROS.[7,25]

The introduction of TKIs in the treatment of Ph+ ALL has led to a dramatic improvement in outcome, as demonstrated by results from the Children's Oncology Group (COG) AALL0031 trial.[25] The following sections focus on further examples of the development of novel approaches to treat children with HR-ALL; these approaches have in part been the result of the collaborative TARGET (Therapeutically Applicable Research to Generate Effective Treatments) initiative (see Table 7-1).

Connectivity Map and Steroid Resistance

Genome-wide analyses of gene expression profiles by means of high-density microarrays provide powerful tools to study mechanisms of drug action. This approach offers the opportunity to identify previously unknown drug targets. The feasibility of this method has been demonstrated in studies of several hematologic diseases. For example, pharmacogenomic studies have shed light on the biologic basis of treatment failure in childhood ALL, by investigating gene expression signatures that were associated with in vitro sensitivity of diagnostic ALL cells to prednisolone, vincristine, L-asparaginase, and daunorubicin. Of note, only a few of the identified intrinsic drug resistance genes had been previously linked to drug resistance, and the identified gene expression signatures discriminated patients who were at higher risk for relapse.[7]

A novel approach was used to computationally connect disease-associated gene expression signatures (e.g., ALL blast cells that are intrinsically sensitive or resistant to glucocorticoid [GC]-induced apoptosis in vitro) to drug-associated gene expression profiles (i.e., the so-called Connectivity Map) in order to identify molecules that reverse a drug-resistance signature.[26] This strategy builds on prior

Table 7-2 Selected Pharmacogenetic Defects That Lead to Adverse Drug Reactions Manifesting as Hematologic Disorders

Adverse Drug Reaction	Drug(s) That Cause ADR	Altered Protein	Important Genetic Variant(s)	Hypotheses on Pathophysiology
Myelosuppression	6-Mercaptopurine 6-Thioguanine azathioprine	Thiopurine-6-methyltransferase (TPMT)	TPMT*2: 238G>C; TPMT*3A: 460G>A; 719A>G; and TPMT*3C: 719A>G	In hematopoietic cells, TPMT inactivates cytotoxic thioguanine nucleotides (TGNs) by methylation. Accumulation of TGNs due to the functionally defective TPMT variants causes hematotoxicity (see text for details).
Myelosuppression (diarrhea)	Irinotecan (CPT-11) Active metabolite: 7-ethyl-10-hydroxycamptothecine (SN-38)	UDP-Glucuronosyltransferase (UGT) isoenzyme 1A1 (UGT1A1)	UGT1A1*28: promotor polymorphism; dinucleotide insertion in the TATA box [wild-type: $(TA)_6TAA$] resulting in $(TA)_7TAA$	The cytotoxic metabolite of CPT-11, SN-38, is mainly inactivated by UGT1A1. Accumulation of cytotoxic SN-38 in hematopoietic and intestinal cells is due to decreased inactivation (glucuronidation) by the variant enzyme.
Myelosuppression (mucositis, neurotoxicity)	5-flourouracil (5-FU)	Dihydropyrimidine Dehydrogenase (DPD)	DPYD*2A: G to A mutation in the invariant GT splice donor site flanking exon 14 (IVS14+1G>A), leading to skipping of exon 14 during splicing	DPD is the rate-limiting enzyme in 5-FU catabolism. Skipping exon 14 during splicing renders the enzyme inactive and can, therefore, be one cause of severe 5-FU toxicity due to prolonged 5-FU exposure.
Venous thrombosis	Oral contraceptives	Prothrombin (FII, F2)	Factor II 20210G>A; SNP in the 3 untranslated region (UTR) at position 20210	Factor II 20210G>A causes elevated prothrombin level, which a risk factor for thrombosis. Oral contraceptives are an additional independent risk factor, and both (FVL) raise the risk for thrombosis
Venous thrombosis	Oral contraceptives	Factor V (FV, F5)	FVL: 1691G>A (in exon 10 of the FV gene) leads to Arg506Gln change lies within the activated protein C cleavage site	FVL causes activated protein C resistance, which is a thrombotic risk factor. Oral contraceptives are an additional independent risk factor, and both (+ factor II 20210G>A) raise the risk for thrombosis.
Bleeding risk	Warfarin and other coumarin derivatives	Cytochrome P450 isoenzyme 2C9 (CYP2C9)	CYP2C9*2: 430C>T in exon 3 leads to an Arg144Cys change. CYP2C9*3: 1075A>C in exon 7 leads to an Ile359Leu change.	CYP2C9 is the most important enzyme in the catabolism of S-warfarin. The CYP2C9*3 allele leads to an amino acid change in the substrate binding site, a decrease in enzyme activity (additionally seen in CYP2C9*2 allele), and an accumulation of S-warfarin, which enhances the risk for bleeding.
Bleeding risk	Clopidogrel	CYP2C19	CYP2C19*17: -806C>T	The prodrug clopidogrel is activated via CYP2C19. CYP2C19*17 results in enhanced transcription and higher enzyme activity, leading to enhanced drug activation and platelet inhibition (ultrarapid metabolizers).

Ig, Immunoglobulin; *SNP,* single-nucleotide polymorphism; *UDP,* uridine diphosphate.
*Nucleotide bases: *A,* adenine; *C,* cytosine; *G,* guanine; *T,* thymine.

findings that small molecules can induce treatment-specific changes in gene expression in leukemia cells in vivo. Indeed, the profile induced by the mTOR inhibitor rapamycin was found to match the signature of GC sensitivity in ALL cells.[7] Moreover, it was shown that rapamycin sensitized a resistant leukemia cell line to GC-induced apoptosis via a modulation of antiapoptotic protein MCL1. This is consistent with earlier work revealing MCL1 overexpression in steroid-resistant ALL. This work suggests that GC in combination with rapamycin could be an effective approach to overcome intrinsic GC resistance in ALL and provides evidence that such a chemical genomic approach based on gene expression might be useful to identify molecules with the potential to overcome intrinsic drug resistance in leukemia.[7]

FMS-Like Tyrosine Kinase-3 (FLT3) and FLT3 Inhibitors

The FMS-like tyrosine kinase-3 (FLT3) is a class III receptor tyrosine kinase (RTK) and is primarily expressed in early myeloid and lymphoid progenitors, where it plays an important role in their proliferation and differentiation. Activating mutations and overexpression of TKIs are well known to be involved in the pathogenesis of many hematologic malignancies. For example, internal-tandem duplications (ITDs) in the FLT3 gene, which led to constitutive activation of FLT3, are found in up to 30% of patients with AML, and FLT3-ITD–positive AML is associated with a poor response to chemotherapy and a poor prognosis.[25]

Using genome-wide gene expression analyses, the FLT3 wild-type gene was identified as being overexpressed in MLL-rearranged and hyperdiploid childhood ALL. FLT3 inhibitors have been shown to inhibit growth in cells that overexpress FLT3, and infants with MLL-rearranged ALL and high FLT3 expressions have been identified to have a very poor prognosis when treated with standard ALL medications. Thus the inclusion of FLT3 inhibitors seems worthy of being investigated in the treatment of children with the poor-prognostic ALL subtype with MLL rearrangements and perhaps those with hyperdiploid ALL, which also overexpresses FLT3. Indeed, the COG trial AALL0631 already investigates the combination of the FLT3

inhibitor lestaurtinib in combination with an intensive chemotherapy backbone in children with MLL-rearranged infant ALL, and this approach may help to improve outcome in this poor-prognostic ALL subtype.[25]

Janus Kinases (JAKs) and JAK Inhibitors

Janus kinases (JAKs) are a family of tyrosine kinases (JAK1, JAK2, JAK3, and nonreceptor protein-tyrosine kinase 2 [TYK2]) that associate with the intracellular tail of cytokine receptors and activate downstream signaling via the STAT family of transcription factors, which bind specific promoters that regulate proliferation and differentiation.

It has long been recognized that the JAK-STAT pathway is essential in hematopoiesis, and its deregulation may play an important role in hematologic malignancies. Indeed, in 2005, a recurrent somatic gain-of-function mutation in the JAK2 gene (1849G>T, rs77375493, V617F) was discovered in a significant proportion of patients with myeloproliferative neoplasms (MPNs)—polycythemia vera (PV), more than 95%; essential thrombocytosis (ET), approximately 50%; and primary myelofibrosis (PM), approximately 40%; this led to the development of JAK2 inhibitors. It is important to note that the JAK-STAT pathway is essential for normal hematopoiesis, and blocking wt-JAK can lead to potentially severe hematologic and/or immunologic side effects; thus inhibitors that selectively target mutant JAK would be an attractive alternative. Early trials with the JAK inhibitor ruxolitinib have already shown clinical benefits in MPN, with manageable toxicity (primarily decreased erythropoiesis and thrombopoiesis); JAK inhibitors, however, have not thus far shown disease-modifying activity, and results of future trials and research will clarify their role in the treatment of MPN.[27] Whereas variants in the JAK genes are often found in myeloid neoplasms, their occurrence seems to be rare in lymphoid neoplasms.

In childhood ALL, however, JAK mutations have recently been identified in a subcohort of children with HR-ALL. This exciting discovery began with genome-wide gene expression analyses that identified a subtype of HR-ALL, which has a gene expression profile similar to that of BCR-ABL1 positive (Ph+) ALL. In contrast to Ph+ ALL, leukemia cells in the identified subtype do not harbor the BCR-ABL1 fusion gene; therefore this HR-ALL subtype has been named BCR-ABL1–like ALL.[25] It was speculated that genetic alterations that can influence tyrosine kinase signaling pathways similar to those downstream of BCR-ABL1 might be involved in the pathogenesis of BCR-ABL1-like ALL; indeed, alterations in the lymphoid transcription factor gene IKZF1 (encoding IKAROS), the lymphoid signaling receptor gene CRLF2 (encoding cytokine receptor like factor 2), and the JAK family of tyrosine kinases, have been identified. Activating mutations in JAK2 (rare in JAK1 and JAK3) have been identified in approximately 10% of children with HR-ALL, and these mutations have been shown to result in increased sensitivity to JAK inhibitors in vitro.[28] Therefore the combination of JAK inhibitors with an intensive chemotherapy backbone seems to be an attractive strategy to improve outcomes in a subgroup of children (those who have activating JAK mutations) with HR-ALL.

FUTURE DIRECTIONS

Pharmacogenomics has already proven to be an important approach to improve drug therapy, and as of August 2011, the FDA has included information on pharmacogenomic biomarkers in the labels of more than 70 drugs. A full list of these medications and further details are available at the FDA's Web site (see Table 7-1). There is, however, a relatively slow pace of translating pharmacogenomics into clinical practice. Laboratory tests (e.g., liver and kidney function tests) are widely used to adjust drug dosages, but even though technology for testing relevant pharmacogenomic biomarkers is widely available, simple, robust, and inexpensive genotyping tests are rarely used to adjust drug dosage.[29] A major difference among these tests is the time lag from the blood sampling to the result. As genotyping becomes faster and cheaper, this issue may no longer be an obstacle. In addition, educative and legislative initiatives and the implementation of user-friendly decision support systems will help to make pharmacogenomic biomarkers a routine part of clinical care. A major advantage to the use of biomarkers is that a patient's genotype, unlike a renal function test, needs to be performed only once in a patient's lifetime.

The recent unprecedented gain of insights into the human genome and genomic variations among individuals has already changed the practice of medicine. High-throughput technologies, such as hybridization-based microarray approaches and next-generation sequencing (NGS) technologies,[6] are available for genome-wide analyses of genomic variants, gene expression patterns, epigenetic patterns, and proteomic and metabonomic profiles. The recent application of these genome-wide tools has already yielded novel insights into drug actions and led to important drug discoveries.

Moreover, these tools are being used to elucidate differences between genomes of normal cells and cancer cells (e.g., the Pediatric Cancer Genome Project; see Table 7-1), and this knowledge has the potential to illuminate paths toward novel prognostic markers (those that can be used for risk stratification in clinical trials) and/or novel therapeutic targets (those that can be used to discover new medications).

Once novel candidate genes have been identified via GWA studies, functional investigations such as systematic mutagenesis, RNA interference, use of overexpression systems (cDNA, open reading frame [ORF] and miRNA expression libraries), and chemistry-based approaches are necessary to establish valid pharmacogenomic mechanisms.[30] The outputs of such studies will advance understanding of the pharmacology of existing medications and will help to identify genes and pathways involved in drug resistance and novel therapeutic targets.

One important consideration in modern medicine is that clinically useful approaches must also be cost-effective. About a decade ago, the cost for the first full human genome sequence was approximately $3 billion; within the next decade, this cost is expected to be about $1000. The markedly lower cost for robust genotyping points to an exciting future for pharmacogenomics research and translation, suggesting that the current approach to selecting medications (often "trial and error") will continue to evolve into more scientific methods for selecting the optimal medications and doses for individual patients—with genomics playing an increasing role in such therapeutic decisions.

CHAPTER 8

HEMATOPOIETIC STEM CELL BIOLOGY

John P. Chute

Hematopoietic stem cells (HSCs) are characterized by their unique ability to self-renew and give rise to the entirety of the blood and immune system throughout the lifetime of an individual.[1-3] HSCs are very rare cells, representing approximately one in 100,000 bone marrow (BM) cells in the adult.[4] The concept of the existence of an HSC that is capable of reconstituting hematopoiesis in vivo was first introduced more than 60 years ago, when Jacobsen et al[5] demonstrated that lead shielding of the spleen protected mice from otherwise lethal γ irradiation.[5] Subsequently, Jacobsen and colleagues[6] demonstrated that similar radioprotection of mice could be achieved via shielding of one femur. Shortly thereafter, it was demonstrated that intravenous injection of BM cells also provided radioprotection of lethally irradiated mice.[7] Interestingly, investigators initially hypothesized that the radioprotected spleen or BM provided soluble factors that mediated radiation protection.[8,9] However, subsequent experiments by Nowell et al[10] and Ford et al[11] critically demonstrated that transplanted BM cells provided radioprotection directly via cellular reconstitution of the blood system. The historical significance of these studies cannot be overestimated because they provided the basis for not only the ultimate isolation and characterization of HSCs but also for the field of hematopoietic cell transplantation.

Subsequent landmark studies by Till and McCulloch[12] demonstrated that transplantation of limiting doses of BM cells gave rise to myeloid and erythroid colonies in the spleens of irradiated recipient mice. Importantly, Till and McCulloch showed that the numbers of colonies detected in recipient mice was proportional to the numbers of BM cells injected into the irradiated mice, suggesting that a particular population of hematopoietic cells was capable of reconstituting hematopoiesis in vivo.[12-14] The clonogenic nature of a subset of BM cells was definitively shown when these investigators irradiated BM cells and then transplanted the cells into lethally irradiated mice. Persistent chromosomal aberrations were demonstrated in spleen colonies in recipient mice.[15] It was subsequently shown that cells within the spleen colonies were radioprotective of lethally irradiated mice and contained myeloid, erythroid, and lymphoid cells.[12,16] Taken together, these data strongly suggested the presence of hematopoietic stem or progenitor cells that were capable of in vivo engraftment and provision of multilineage progeny from a small number of parent cells.[17]

EMBRYONIC ORIGIN OF HEMATOPOIETIC STEM CELLS

During embryogenesis, cells from the ventral mesoderm migrate to the extraembryonic yolk sac, wherein primitive hematopoiesis occurs at **E7.5.**[4] Primitive hematopoiesis in mammals is transient and encompasses the generation of primarily erythroid cells and macrophages.[4,18] Careful anatomic analysis has demonstrated erythroid cells and vascular endothelium in close proximity during primitive hematopoiesis, suggesting perhaps a common cell of origin or hemangioblast.[4] Early studies by Shalaby et al[19,20] showed that mice lacking Flk1, a tyrosine kinase expressed on endothelial progenitor cells (EPCs), failed to develop both vascular endothelium and blood islands during embryogenesis. Choi et al[21] subsequently demonstrated via gene tracing studies in vitro that vascular endothelial and hematopoietic cells arose from a common precursor cell, the hemangioblast. More recently, studies of human embryonic stem cells (ESCs) revealed that cytokine stimulation of human ESCs can induce the development of cells with both hematopoietic and vascular features.[4,22] Taken together, these studies suggest that a cell consistent with a hemangioblast provides the origin of primitive hematopoiesis in mammals.

In contrast to the extra-embryonic origin of primitive hematopoiesis, definitive hematopoiesis originates in the intraembryonic aorto–gonado–mesonephros (AGM) region.[4,19,21,23,24] The onset of definitive hematopoiesis was shown by several different investigators to occur at the site of the dorsal aorta at **E10.5-11.5** within the AGM region.[23,24] Several complementary studies using lineage tracing experiments in both mice and zebrafish have subsequently demonstrated that HSCs arise from hemogenic endothelium within the ventral aspect of the dorsal aorta.[25-27] Runx1 is required for this process to occur in mice,[28] and HSCs that arise from hemogenic endothelium migrate properly to the fetal liver and to the BM and are capable of self-renewal and multilineage differentiation.[25]

DEFINITION OF HEMATOPOIETIC STEM CELLS

Phenotype

Murine Hematopoietic Stem Cells

The HSC is the most well-defined somatic, multipotent cell in the body. With the emergence of antibody technology and flow cytometry[17,29,30] and coupled with *in* vitro and in vivo functional assays,[31-36] biologists have developed reproducible methods to analyze and isolate murine and human HSCs with a high level of enrichment. In mice, Weissman and colleagues were able to show that antibody-based depletion of BM cells expressing myeloid, B cell, T cell, and erythroid cells along with positive selection for cells expressing c-kit, sca-1, and Thy1.1^{lo} ("KTLS" cells), allowed for enrichment for HSCs to approximately 1 of 10 to 30 cells as measured by the capacity to provide long-term, multilineage hematopoietic reconstitution in a competitively transplanted, lethally irradiated congenic mouse.[32,37-40] Because Thy 1.1 is not expressed on many strains of mice,[38] additional markers were developed, including Flk2 (Flt-3), the absence of which was shown to substantially enrich for murine LT-HSCs.[41,42] Similarly, it has been demonstrated that the isolation of murine BM KSL cells based upon the lack of expression of CD34 (34$^-$KSL) enriches for HSCs with long-term reconstituting capability at the level of one of 5 to 10 cells (Fig. 8-1).[43]

An alternative and effective method for isolating BM HSCs involves the use of intravital dyes, Hoescht 33342 and Rhodamine 123.[44-48] HSCs, unlike more committed progenitor cells, efficiently efflux these dyes such that HSCs display low-intensity staining for these dyes.[48,49] Li and Johnson[47] demonstrated that HSCs capable of long-term, multilineage repopulation in lethally irradiated mice were significantly enriched in the Rhodamine 123 lo Sca-1+Lin- cells, but Rho hi Sca-1+Lin- cells possessed little repopulating activity. Similarly, McAlister et al[46] showed that isolation of Hoescht lo BM mononuclear cells significantly enriched for both CFU-S14 and cells capable of radioprotection and multilineage reconstitution in lethally irradiated mice. A subsequent and important refinement in the use of Hoescht 33342 (Ho 33342) to isolate HSCs was made by Goodell

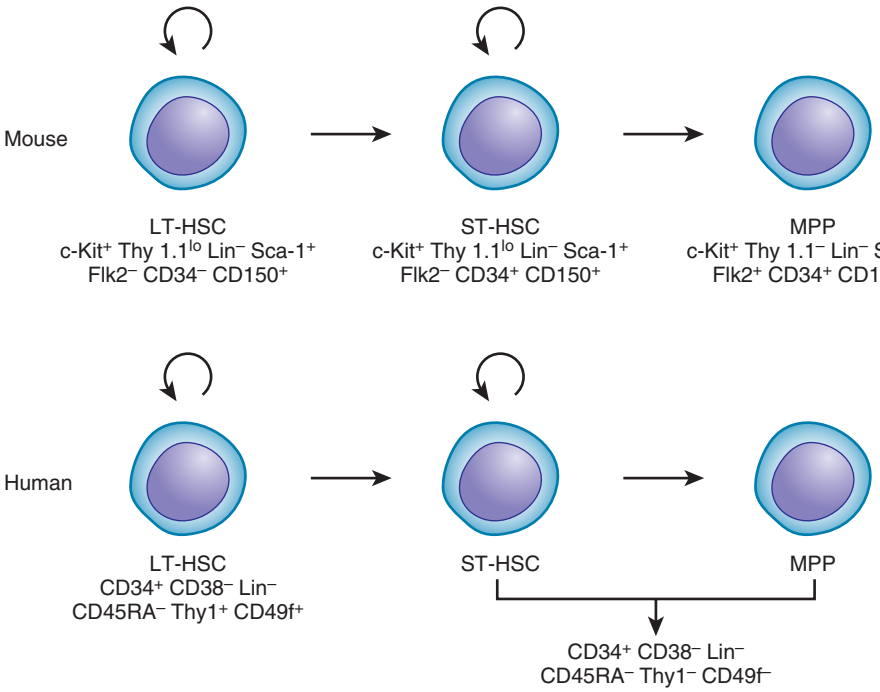

Figure 8-1 PHENOTYPE OF MURINE AND HUMAN HEMATOPOIETIC STEM CELLS (HSCs). Long-term HSCs (LT-HSCs), short-term HSCs (ST-HSCs), and multipotent progenitor cells (MPPs) have precise cell surface markers that discriminate them from more committed progenitor cells. *(Adapted from Prohaska S, Weissman I: Chapter 5. Biology of hematopoietic stem and progenitor cells. In Appelbaum FR, Forman SJ, Negrin RS, et al, editors:* Thomas' Hematopoietic Cell Transplantation, *ed 4, 2009, John Wiley and Sons.)*

et al,[48] who showed that a Ho 33342 side population (SP) can be identified via the emission of Ho 33342 at 2 wavelengths, which yields a tail profile on flow cytometric analysis. Importantly, isolation of Ho 33342 SP cells has been shown to yield variable enrichment for HSCs compared with 34$^-$Flt3$^-$KSL cells, and this may be caused by the sensitivity of the assay to variations in staining techniques and batch-to-batch differences in Hoescht 33342 dye.[50-52] However, Matsuzaki et al[53] demonstrated that transplantation of single Ho 33342 SP 34$^-$KSL cells into lethally irradiated C57Bl6 mice yielded donor cell multilineage engraftment greater than 1% in more than 95% of transplanted mice. Therefore, the combination of Ho 33342 SP cells with 34$^-$KSL markers provides a basis for isolation of highly enriched LT-HSCs from mice.[29,50,52]

A major advance in this field involved the discovery by Kiel et al[54] that the surface expression of CD150, a member of the signaling lymphocyte activation molecules (SLAM) family, significantly enriched for murine BM HSCs. It was also shown that the absence of CD41 and CD48 on CD150$^+$ cell enriches further for the HSC population and that CD150$^+$CD41$^-$CD48$^-$KSL cells reconstitute approximately half of all mice competitively transplanted with limiting numbers of cells.[54] Taken together, isolation of SLAM$^+$KSL BM cells has become a reproducible and efficient strategy to isolate murine LT-HSCs with maximal enrichment (see Fig. 8-1).[55]

Although this chapter focuses on the phenotypic and functional characterization of HSCs, it is worth noting that some controversy exists regarding whether adult T-cell progenitors possess myeloid potential.[56-58] It was independently suggested by Bell et al[57] and Wada et al[56] that adult T-cell thymic progenitors possessed myeloid differentiation potential. However, whereas these studies primarily involved in vitro culture of T cells on stromal cells, subsequent in vivo transplantation studies failed to demonstrate the myeloid potential of adult T cells.[58] Taken together, these data suggest that although common lymphoid progenitors may possess myeloid differentiation potential, it may not be physiologically relevant but rather may be an artifact of specialized co-culture conditions.[58] Recent studies have also clarified the nature of common lymphoid progenitor cells (CLPs) and has dissected this population further into an all-lymphoid progenitor (ALP) cell, which retains full lymphoid potential and thymic seeding capability, and B lymphoid progenitor cells (BLPs), which is restricted to the B-cell lineage.[59] Whereas ALPs are characterized by the lack of surface expression of Lyd6, BLPs demonstrate expression of Lyd6 and upregulate the B-cell–specific factors, Ebf1 and Pax5.[59] The phenotypic markers of the hematopoietic hierarchy through myeloid and lymphoid differentiation are shown in Fig. 8-2.

Human Hematopoietic Stem Cells

Significant progress has also been made in the phenotypic characterization of human HSCs via flow cytometric analysis combined with in vivo transplantation assays in immune-deficient mice.[60,61] Of particular note, although murine HSCs can be characterized by the absence of CD34 expression on the cell surface, human HSCs are primarily enriched using CD34 surface expression, and this provides the basis for confirming sufficient HSC content to allow for successful hematopoietic cell transplantation in patients.[17,62,63] There is also some controversy in this area because some investigations have suggested that LT-HSCs can be isolated from CD34$^-$ human hematopoietic cells.[64-67] Of note, only a small percentage (<0.1%) of CD34$^+$ human hematopoietic cells possess the capacity to engraft following intravenous injection into nonobese diabetic/severe combined immune deficient (NOD/SCID) mice.[4,61] Further enrichment of human HSCs has been demonstrated via negative selection for surface expression of CD38 and depletion of lineage surface markers.[61,68,69] Thy 1.1 (CD90) surface expression also enriches for multilineage colony-forming ability and in vivo reconstituting capacity of human hematopoietic cells.[17,70] Majeti et al showed that the CD34$^+$ CD38$^-$Thy1.1$^+$CD45RA$^-$lin$^-$ population in human cord blood (CB) was enriched at the level of 1 in 10 cells for LT-HSCs.[70] The authors also showed that candidate multipotent progenitor cells (MPPs) were demarcated by the CD34$^+$CD38$^-$Thy1.1$^-$CD45RA$^-$lin$^-$ population, suggesting that the loss of Thy1.1 reflects the transition of LT-HSCs to ST-HSCs/MPPs.[17,70]

CD49f$^+$ Human Hematopoietic Stem Cells

Although it is possible to enrich murine BM HSCs to the level of nearly single-cell purity using various combinations of cell surface

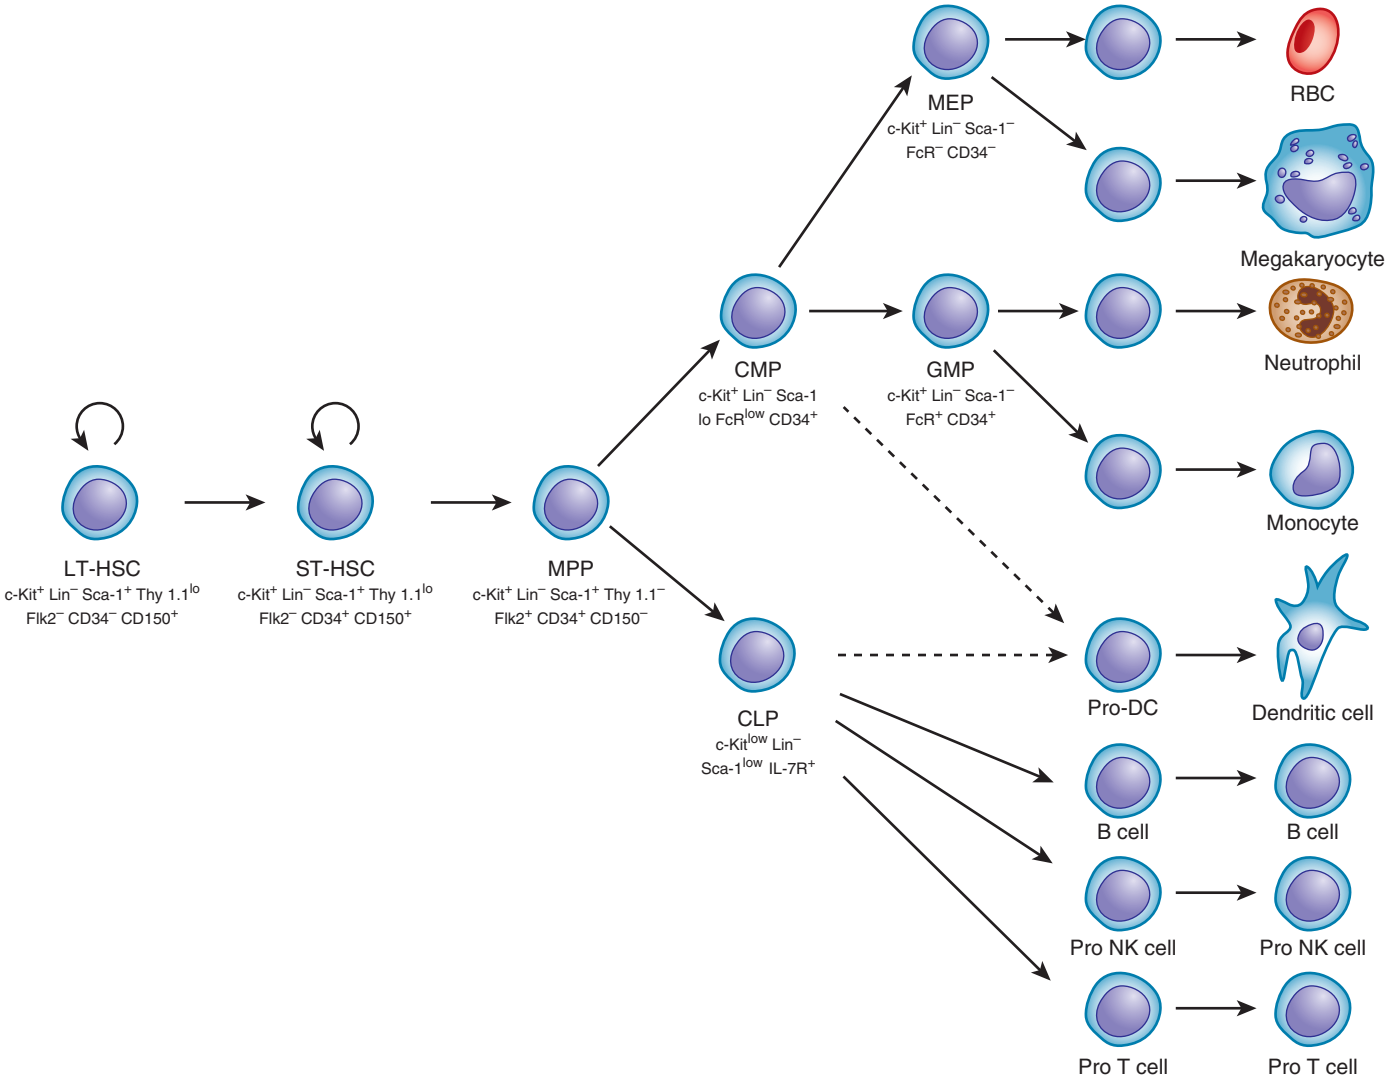

Figure 8-2 HEMATOPOIETIC CELLULAR HIERARCHY. The phenotypes of murine hematopoietic stem cells (HSCs) and committed progenitor cells are shown. *CLP,* Common lymphoid progenitor cell; *CMP,* common myeloid progenitor cell; *DC,* dendritic cell; *GMP,* granulocyte-macrophage progenitor cell; *MEP,* megakaryocytic-erythroid progenitor cell; *NK,* natural killer; *RBC,* red blood cell. *(Adapted from Prohaska S, Weissman I: Chapter 5. Biology of hematopoietic stem and progenitor cells. In Appelbaum FR, Forman SJ, Negrin RS, et al, editors:* Thomas' Hematopoietic Cell Transplantation, *ed 4, 2009, John Wiley and Sons.)*

markers, isolation of human BM HSCs to the same level of purity has not been achieved.[48,54,71] However, a recent study indicates that intrafemoral injection of a FACS-purified population of human CB $CD34^+CD38^-CD45RA^-Thy1^+$ cells that were additionally purified based on surface expression of the integrin α6 ($CD49f^+$) yielded 6.7-fold increased human donor chimerism at 20 weeks in NOD-SCID IL2R-γ-/- (NSG) mice compared with injection with the identical dose of $CD34^+CD38^-CD45RA^-Thy1^+CD49f^-$ cells.[72] Only the $Thy1^+CD49f^+$ cells could be serially transplanted in this study, and the enrichment for LT-HSCs via limiting dilution analysis was estimated to be approximately 1 in 11 $CD34^+CD38^-CD45RA^-Thy1^+CD49f^+$ cells.[72] Further purification of this population of cells using Rhodamine dye demonstrated that single-cell transplantation of $Thy1^+Rho^{lo}CD49f^+$ cells yielded long-term, multilineage engraftment in 5 of 18 transplanted recipients. Serial transplantation was also successful in two of four secondary mice, suggesting that at least some of the $Thy1^+Rho^{lo}CD49f^+$ cells undergo self-renewal.[72] Of note, because mice were transplanted via intrafemoral injection in these studies, it remains unknown whether this panel of markers equally identifies human HSCs capable of homing properly to the BM after intravenous injection. Nonetheless, these studies reveal that the addition of $CD49f^+$ to the panel of human LT-HSC markers provides an improved capability to isolate human HSCs at a level of purity that is comparable to that applied to murine HSC isolation.

FUNCTIONAL ASSAYS

In Vitro Assays

The colony-forming cell (CFC) assay does not measure HSC content but rather committed myeloid progenitor cell content via a 14-day assay for colonies within methylcellulose media that is supplemented with specific growth factors.[52] The CFC assay measures CFU–granulocyte monocyte (CFU-GM), burst forming unit-erythroid (BFU-E) and CFU–granulocyte, erythroid, macrophage, megakaryocyte (CFU-GEMM). The CFU-GEMM, or CFU-mix colonies, represent a more immature progenitor cell population. B- and T-cell progenitor cell content can also be measured via in vitro assay but requires specialized co-culture conditions, which are described elsewhere.[52,73,74]

The long-term culture-initiating cell (LTC-IC) assay is a 6-week in vitro assay in which BM cells are co-cultured with murine stromal cells for 4 weeks followed by replating of the entire culture system into methylcellulose and additional 2-week assay for colony formation.[52,75] The LTC-IC, unlike the CFC, measures a more immature stem/progenitor cell population, although the results of the LTC-IC are inherently dependent and limited by technical variabilities in stromal co-culture experiments.[52] Importantly, the LTC-ICs lack

long-term repopulating cells because transplantation of LTC-ICs into mice in a competitive transplantation assay does not result in any long-term reconstitution.[52,60]

The cobblestone area–forming cell (CAFC) assay also involves co-culture of HSCs with preestablished stromal cell monolayers and relies on microscopic quantification of cobblestone-forming cells embedded underneath the stromal layer.[75,76] It has been shown that CAFC content correlates well with CFU-S-12 content and marrow repopulating capacity.[52,75] However, similar to the LTC-IC, the CAFC assay does not measure LT-HSCs. An advantage of the CAFC and LTC-IC assays is that the estimate of stem/progenitor cell content is not confounded by the homing capacity of the cell population being tested. However, competitive transplantation assays provide a more physiologically relevant measure of functional HSC content and allow quantification of LT-HSC content as well as homing efficiency.[38,52,77]

In Vivo Assays

Colony-Forming Unit–Spleen Assay

The first reproducible in vivo assay for hematopoietic progenitor cells was the CFU–spleen assay (CFU-S), which was developed by Till and McCullough.[12,62] In this assay, BM cells are injected into lethally irradiated mice, and macroscopic spleen colonies are measured from 1 to 3 weeks after injection.[52] These colonies represent short-term repopulating cell and MPP activity but do not measure long-term HSC content.[4,52]

Competitive Repopulation Assay

A significant advance in the study of hematopoiesis was the development of the competitive repopulating assay.[52,78] In this assay, an unknown population of hematopoietic cells is transplanted via intravenous injection into lethally irradiated syngeneic mice along with a competing dose of host-derived BM cells.[52,79,80] This assay has been refined over time such that it is typically performed using a limiting dilution method in which several cell doses (typically >–three to five doses; n = 10 mice/dose level) of BM cells or purified HSCs (e.g., 34^{-}KSL cells) are injected into lethally irradiated mice along with a fixed dose of host competitor BM cells, such that a fraction of the recipient mice can be predicted to have non-engraftment.[52,81,82] This approach allows the application of Poisson statistical analysis to provide an estimate of competitive repopulating units (CRUs) within the donor hematopoietic cell population.[52,81-83] An important feature of the CRU assay is the potential to estimate the frequency of LT-HSCs in a given hematopoietic cell population. Donor cell engraftment that is detected within the first 8 to 12 weeks after transplantation, reflects the contribution of ST-HSCs, which extinguish at or beyond 12 weeks posttransplant. Therefore, measurement of LT-HSC cannot be convincingly estimated until more than 12 to 20 weeks posttransplantation.[52,84] Dykstra et al.[85] showed that competitive transplantation of single, phenotypic HSCs results in stable donor cell engraftment in lethally irradiated mice beyond 16 weeks, and retroviral marking of HSCs revealed that stable donor-derived hematopoiesis was not observed in recipient mice until 6 months posttransplant.

A commonly used and rigorous approach to estimate the presence of LT-HSCs is the performance of secondary, tertiary, and quaternary HSC transplants.[52] This approach is based on the principle that a singular feature of primitive LT-HSCs is the capacity to serially reconstitute multilineage hematopoiesis in vivo without exhaustion.[52,86-88] In this method, whole BM is typically collected from primary recipient mice and then injected, along with host competitor BM cells, into lethally irradiated syngeneic mice. Donor cell repopulation is then measured at 12 to 20 weeks posttransplantation. Serial transplantation assays have the limitation of being potentially confounded by variables such as homing efficiency of the donor cells.[52,89,90] Therefore, as pointed out by Purton and Scaddon[52] in an excellent review of this subject, serial transplantation assays may be better suited to studies of wild type hematopoietic cell populations as opposed to mutant mice-derived hematopoietic cells, which may have alterations in homing or engraftment mechanisms independent of HSC content.[52] Utilization of whole BM avoids issues regarding the fidelity of phenotypic markers of HSCs in mutant mice and is perhaps more broadly feasible than FACS-isolated HSC populations at some centers.[52,91-94] However, the use of purified HSCs avoids the potential confounding effects of accessory cells contained within the BM graft on donor cell repopulation and allows for precise determination of effects of growth factors on HSC content in vitro compared with unmanipulated BM.[77,95] Lastly, Poisson statistical analysis and estimation of CRU frequency is based on particular criteria for "positive" donor engraftment in recipient mice, typically 0.1 to 1.0% multilineage donor engraftment.[77,96] Therefore, the estimation of CRU frequency can be substantially altered depending on what criteria for engraftment is established. Given the limitations of flow cytometric analysis for accurate multilineage engraftment of hematopoietic cells, it is recommended that a criteria of greater than 1% multilineage engraftment be used for evidence of donor cell repopulation using the competitive repopulating assay.[52]

REGULATION OF HEMATOPOIETIC STEM CELL FATE

Intrinsic Pathways

Transcription Factors

The HSC pool must be maintained throughout the lifetime of an individual to replenish the blood and immune system over time. Sustainment of the HSC pool over time is regulated by both intrinsic and extrinsic mechanisms. Remarkably, numerous transcription factors have been shown to be necessary for HSC self-renewal as measured by competitive transplantation assay.[1] For example, GATA2, GFI1, JunB, PU.1, Myb, CREB-binding protein, Smad4, and ZFX have each been shown to be necessary for maintenance of adult HSCs in vivo.[1,97-104] Zon[1] and others[105] have articulated that a competitive balance exists between transcription factors, thereby providing fine control of HSC self-renewal and differentiation processes. Whether such a balance occurs via direct binding or competition for target genes or modulation of activator–repressor complexes remains unknown.[1] However, the interaction of PU.1, which drives myeloid differentiation,[105] and GATA1, which drives erythroid differentiation, provides an example as to how transcription factors can govern progenitor cell fate.[1,106,107] PU.1 and GATA1 can bind each other as a means of preventing binding of lineage-specific target genes, and lineage differentiation has been shown to be directly related to the levels of PU.1 and GATA1 in the cell.[1]

Recent studies have implicated numerous intracellular proteins as regulators of HSC content in vivo. For example, genetic deletion of the cyclin-dependent kinase inhibitor, p21, resulted in an expansion of the HSC pool in vivo, but BM cells from $p21^{-/-}$ mice demonstrated impaired capacity for serial transplantation. Therefore, p21 appears to be essential for maintenance of LT-HSCs in vivo.[108] Similarly, genetic deletion of PTEN, a negative regulator of the PI3K-Akt pathway, resulted in expansion of ST-HSCs in mice but depletion of LT-HSCs with serial repopulating capacity.[109] Interestingly, Akala et al showed that deletion of the cyclin dependent kinase inhibitors, p16Ink4a and p19Arf, along with p53 in mice yields a 10-fold increase in BM cells capable of long term hematopoietic repopulation.[110,111] These results suggest that p16, p19, and p53 have an important function in controlling the expansion potential of BM stem/progenitor cells.[110] Taken together, these results indicate that targeting of intracellular proteins that regulate HSC proliferation has therapeutic potential as a means to expand the HSC pool.[111,112]

HOX PROTEINS

HOX proteins have been shown to be necessary for normal development in *Drosophila* and mice.[1] Several proteins within the HOX

family, including HOXB4, HOXA9, and HOXA10, have been shown to have an important role in the induction of HSC self-renewal.[113-115] Virally-mediated overexpression of HOXB4 in mouse HSCs causes a pronounced (>40-fold) expansion of HSCs in vitro and in vivo.[116,117] Nonviral culture with a TAT-HOXB4 protein also induces a four- to sixfold amplification compared with input HSC numbers after 4-day culture, suggesting the translational potential of expanding HSCs using this approach.[116] An important aspect of *HOXB4* overexpression is the apparent lack of development of leukemia in mice transplanted with *HOXB4*-overexpressing hematopoietic cells followed long term.[116,117] Enforced expression of *HOXA9* also promotes the expansion of adult HSCs.[114] However, mice transplanted with BM cells that overexpress *HOXA9* develop leukemia over time.[1,118] Overexpression of other *HOX* genes, including *HOXA10 and HOXA7,* have also been shown to induce HSC expansion[1,119]; however, overexpression of *HOXA10* blocks myeloid and lymphoid differentiation and leads to acute myeloid leukemia.[120] Recently, Ohta et al[121] reported that retroviral-mediated overexpression of NUP98/HOXA10 fusion protein in murine BM ckit$^+$sca-1$^+$lin$^-$ (KSL) cells caused more than 1000-fold expansion of HSCs in 10-day cultures. Interestingly, mice that are deficient in HOXB4 or HOXB3 display only a mild proliferative defect in HSCs,[122,123] and HOXA9-deficient mice demonstrate moderate decreases in leukocyte counts but no effects on HSC content.[124] However, compound deletion of *HOXA9, HOXB4,* and *HOXB3* in mice causes severe hematopoietic defects.[125] These results suggest that although overexpression of *HOX* genes can induce HSC self-renewal and, in some cases, leukemogenesis,[1,118,119,126] these genes are not necessary for HSC self-renewal and can be compensated for by other mechanisms.

Importantly, *HOX* gene expression is regulated by members of the caudal-type homeobox (CDX) proteins, which can bind to and activate *HOX* gene expression.[1,127] The homeobox protein, MEIS 1, and the homeodomain protein, PBX, also regulate *HOX* gene expression.[1,118] Davidson et al[127] demonstrated that zebrafish lacking CDX4 failed to generate HSCs during development, and these mutants could be rescued from this phenotype by delivery of *HOXA9* mRNA.[1] Similarly, Schnabel et al[118] showed that HOXA9-mediated expansion of hematopoietic progenitor cells required expression of PBX and MEIS1 motifs.[1] Taken together, these results demonstrate the important role of CDX, PBX, and MEIS1 in regulating HOX-protein activity in the hematopoietic system.

Epigenetic Regulation of Hematopoietic Stem Cells Self-Renewal

In the steady state, most DNA in a cell is inaccessible to the transcriptional machinery, coiled in tightly packed chromatin, but certain active genes are highly accessible.[1,128,129] The accessibility of genes to transcriptional activity is regulated by several factors, including methylation status, histone modification, and nucleosome activity. During development, cells undergo processes in which they progressively lose pluripotency and become committed to various lineages.[128,129] It has now been demonstrated that this process is regulated substantially via epigenetic mechanisms. For example, it has been shown that the enforced expression of OCT4, SOX2, c-Myc, and KLF4 in mouse or human somatic cells can induce the generation of pluripotent stem cells (iPS).[130-137] Kim et al[130] subsequently showed that ectopic expression of an unmethylated copy of OCT4 was sufficient to generate induced pluripotent stem (iPS) cells from human neural stem cells.

Epigenetic regulation has also been shown to be important in the differentiation and the lineage commitment of HSCs.[129] For example, Lck, which encodes a SRC kinase responsible for initiating T-cell receptor signaling, is methylated in HSCs but demethylated in CLPs.[129,138,139] Similarly, myeloperoxidase (Mpo), a microbicidal enzyme important in neutrophils, is methylated in HSCs and demethylated in granulocyte monocyte progenitor cells (GMPs).[129] More importantly, from a functional standpoint, Bröske et al[140] and Trowbridge et al[141] have demonstrated directly that DNA methylation regulates the HSC self-renewal process. Mice with deficient DNA methyltransferase 1 (DNMT1) activity demonstrated severe depletion of BM HSC and progenitor cell content over time and skewed myeloid differentiation in vivo.[140] Similarly, conditional deletion of DNMT1 in the hematopoietic system was shown to block HSC self-renewal and niche retention as measured in a competitive transplantation assays.[141] Interestingly, targeted deletion of DNMT3A or DNMT3B does not affect HSC self-renewal, but deletion of both DNMT3A and DNMT3B causes a repopulating defect in HSCs.[1,142] Therefore, the combination of DNMT3A and DNMT3B is also necessary for normal HSC self-renewal.

Another example of epigenetic modulation of HSC self-renewal is the BMI protein.[1,143-145] BMI1 is a chromatin-associated factor that is a component of the polycomb repressive complex.[1] Mice that are deficient in BMI1 demonstrate exhaustion of HSCs, but overexpression of BMI1 increases HSC self-renewal.[1,143-145] It was also shown that BMI1-deficient mice have markedly increased levels of INK4 (p16), a cell cycle regulator, suggesting that BMI1 represses the expression of this gene.[1,146,147] Therefore, BMI1 may promote HSC self-renewal via repression of cell cycle regulatory genes.[1] Several additional examples of chromatin-associated factors that regulate HSC homeostasis have been described, and this topic is well summarized in the comprehensive review by Cedar and Bergman.[129]

MicroRNA Regulation

An additional and important level of regulation of gene transcription is mediated by microRNAs.[148,149] MicroRNAs are small, noncoding RNAs that regulate gene expression by binding with target mRNAs, yielding transcriptional repression or mRNA destabilization.[148,150-152] MicroRNAs can target hundreds of different mRNAs, and mRNAs have multiple microRNA binding sites, allowing for highly complex regulation of gene expression.[148,153] Array analysis has revealed numerous miRNAs to be enriched in HSCs, including miR-155, miR-125b, miR-126, and miR-130a.[154-157] Several miRNAs have been implicated in regulating hematopoietic progenitor cell differentiation, including miR-155 (lymphoid and myeloid development),[154,158,159] miR-223 (myeloid development),[160,161] and the miR-181/miR-150/miR-17-92 cluster (lymphoid development).[162-165] Recently, Gerrits et al[148] demonstrated that overexpression of the miR cluster of miR-99b/let-7e/125a or miR-125a alone in hematopoietic progenitor cells caused a significant increase in CAFC content in vitro and accelerated myeloid differentiation after transplantation into lethally irradiated mice. In a parallel study, Guo et al[149] reported that this same miRNA cluster was enriched in CD34$^-$Flt-3$^-$KSL cells and that overexpression of miR-125a alone was capable of expanding the HSC pool. Importantly, these authors also showed that miR-125a modulated this expansion of HSCs, at least in part, via inhibition of the pro-apoptotic gene, Bak1.[149] Although numerous additional miRNAs, including miR-125b, miR-29a, and miR-146a, have been implicated in regulating HSC fate,[156,166,167] the critical objective going forward will be to identify and validate the miRNA gene targets in HSCs.[148] This will allow a comprehensive map of miRNA regulation of HSC fate to be developed.

EXTRINSIC REGULATION

The past 3 decades have yielded substantial progress in the discovery and characterization of mechanisms that regulate HSC self-renewal and differentiation. Despite this, the translation of these discoveries into the development of translatable methods to expand human HSCs ex vivo or therapeutics to induce HSC expansion in vivo has proven to be difficult. Therefore, dissection of both intrinsic signaling pathways and extrinsic mechanisms that regulate HSC self-renewal, differentiation, and regeneration continues to be a high priority. The following pathways are extrinsically controlled and reflect unique mechanistic targets for the development of therapeutics to amplify the human HSC pool.

Notch Signaling

The Notch signaling pathway has been shown to have an important role in regulating the development of the central nervous system, eye, mesoderm, and ovaries.[111,168,169] To date, four Notch receptors have been identified (Notch 1-4) as well as five ligands for Notch receptors (Jagged 1 and 2 and Delta 1, 3, and 4).[111,170] Notch ligands bind Notch receptors on HSCs, causing cleavage of the Notch-intracellular domain (NICD), which then translocates to the nucleus and binds with the transcription factor CSL (CBF1/RBPJκ).[111,171] RBPJκ then activates target transcription factors, such as HES1 and HES5,[1,111,172,173] which can inhibit both myeloid and B-cell differentiation. Notch 1 and 2 are expressed on murine and human hematopoietic progenitor cells and BM microenvironmental cells express Jagged 1 and Delta 1, providing the basis for extrinsic regulation of Notch signaling in HSCs in the physiologic niche.[111,174,175] Retroviral-mediated expression of the constitutively active form of the NICD in murine HSCs causes the generation of an immortal, cytokine-dependent cell line capable of multilineage in vivo repopulating capacity,[176] thereby demonstrating that activation of Notch signaling is sufficient to induce HSC expansion.[111] Culture of murine HSCs with immobilized Delta 1 promotes a several-fold expansion of HSCs ex vivo.[177] Similarly, MSCV-mediated or Jagged 2–mediated activation of Notch signaling inhibits the differentiation of human CB $CD34^+$ cells,[178] and culture of human CB HSCs with soluble human Jagged 1 induces HSC expansion ex vivo.[175] Notch signaling also appears to have a role in regulating the physiologic maintenance of the HSC pool in vivo.[179] BM osteoblasts express Jagged 1 and administration of γ-secretase inhibitor significantly decreases murine HSC expansion in BM osteoblast co-cultures.[179] Conversely, deletion of Jagged 1 was shown to have no effect on HSC content in mice, and Notch 1–deficient HSCs displayed normal reconstituting capacity in vivo.[180] Deletion of RBPJ, which is required for canonical Notch signaling, also caused no defect in defect in HSC repopulating capacity.[181] Therefore, although activation of Notch signaling clearly induces HSC expansion, Notch signaling may not be necessary for maintenance of the functional HSC pool.[111,180,181] A schematic overview of Notch 1 and 2 regulation of HSC self-renewal and differentiation is shown in Fig. 8-3.

In keeping with the evidence in mice that activation of Notch signaling can induce HSC expansion, Delaney et al[182] showed that serum-free culture of human CB progenitor cells with immobilized Delta 1 plus cytokines for 3 weeks yielded a 5.3-fold increase in human hematopoietic cell engraftment in transplanted non-obese diabetic/severe combined immunodeficient (NOD/SCID) mice. This group subsequently completed a phase I clinical trial showing that transplantation of CB cells expanded with immobilized Delta 1 along with an unmanipulated CB unit was associated with earlier time to neutrophil recovery (median, 16 days) compared with a cohort that received 2 unmanipulated CB units (median, 26 days).[183] Of note, in this phase I study, the unmanipulated CB cells demonstrated dominant engraftment by day +80 and in seven of eight reported recipients, and ex vivo expanded CB cells were not detectable in recipients by day +40 posttransplant.[183] The extinction of the Delta 1–expanded grafts may have been explained by T-cell depletion of the ex vivo expanded products because donor CB $CD8^+$ T cells have been shown to mediate the rejection of second CB units in the setting of double CB transplantation.[184]

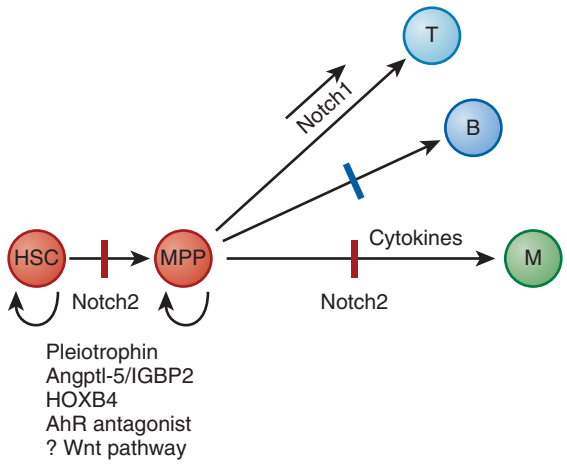

Figure 8-3 MODEL OF NOTCH REGULATION OF HEMATOPOIETIC STEM CELL (HSC) SELF-RENEWAL. Notch2 promotes HSC self-renewal by blocking differentiation into multipotent progenitor cells (MPPs) and the myeloid lineage (M). Notch1 promotes T-cell differentiation and inhibits B-cell differentiation. Molecules and growth factors with proposed roles in regulating HSC self-renewal are also shown. Wnt Signaling

Several lines of evidence implicate Wnt signaling in the regulation of HSC self-renewal and differentiation. First, Wnt proteins have been shown to be expressed at sites of fetal hematopoiesis, and the Wnt-responsive transcription factors, LEF/TCF, are expressed by adult HSCs.[185-187] Using BM from bcl2 transgenic mice,[188] Willert et al[189] showed that treatment of BM $c\text{-}kit^+Thy1.1^{lo}sca\text{-}1^+lin^-$ (KTLS) cells with purified Wnt3a protein differentially maintained cells in culture capable of providing multilineage reconstitution in competitively transplanted recipient mice. Reya et al[187] showed that retroviral-mediated overexpression of the active form of β-catenin, a transcriptional co-regulator which mediates Wnt signaling, in BM KTLS cells from bcl2 transgenic mice resulted in expansion of HSCs capable of multilineage reconstitution in competitively transplanted mice. Furthermore, these investigators showed that overexpression of β-catenin caused upregulation of HoxB4 and Notch 1 in HSCs, suggesting cross-talk between these pathways in regulating HSC self-renewal.[187] In vivo activation activation of Wnt signaling via systemic administration of Wnt5a was also shown to induce a greater than threefold increase in human hematopoietic progenitor cell repopulation in NOD/SCID mice.[190] Of note, no effect of Wnt5a was observed on the ex vivo expansion of human HSCs.[190] Nemeth et al[191] reported that treatment of murine HSCs with Wnt5a inhibited canonical Wnt signaling and maintained HSC repopulating activity in culture via inhibition of HSC cycling. In a related study, culture of human CB cells with an inhibitor of glycogen synthase kinase–3b (GSK-3B), which antagonizes Wnt signaling, failed to expand CB HSCs in culture but did improve CB engraftment in immune-deficient mice when delivered in vivo.[192] Interestingly, although activation of Wnt signaling can induce HSC expansion, it is uncertain whether Wnt signaling is indispensable for normal hematopoiesis to occur. Cobas et al[193] demonstrated that conditional deletion of β-catenin had no significant effect on hematopoiesis in an MxCre-loxP mouse model. Conversely, Zhao et al[194] reported that conditional deletion of β-catenin in VavCre mice caused a deficiency in both HSC growth and maintenance in vivo. The differences observed in these studies may have reflected the different mouse models because administration of polyI-polyC, as required in the MxCre model, can cause HSC toxicity.[195] However, Kirstetter et al[196] also reported that activation of the canonical Wnt pathway under control of the ROSA26 locus led to exhaustion of the HSC pool in vivo. These results raise the possibility that the prior report of HSC expansion in response to retroviral-mediated overexpression of β-catenin may have been affected by the use of bcl-2 transgenic mice.[187] Nonetheless, the abundance of evidence suggests that activation of Wnt signaling is capable of promoting HSC expansion *in* vitro and perhaps in vivo.[185,187,189-191] Importantly, Duncan et al[197] demonstrated that Wnt-mediated maintenance of the HSC pool depended on intact Notch signaling, suggesting a deterministic role for the Notch pathway in controlling the effects of Wnt signaling on the undifferentiated HSC pool.[185]

Smad Signaling Pathway

The Smad pathway represents a signaling mechanism that can be activated by members of the transforming growth factor-β (TGF-β) superfamily and bone morphogenetic proteins.[1,185] TGF-β has strong antiproliferative effects on HSCs, and deletion of TGF-β releases HSCs from quiescence.[198-201] It has been suggested that TGF-β mediates cell cycle inhibition of HSCs via upregulation of cyclin dependent kinase inhibitors, p21 and p57, and downregulation of cytokine receptors.[185,202-209] The role of TGF-β as a negative regulator of hematopoiesis is further supported by the observation that deletion of TGF-β1 causes augmented myelopoiesis in mice.[185,210] Conversely, TGF-β type 1 receptor null mice display normal HSC self-renewal and regeneration in vivo.[185,211,212] These differences between the in vitro activity of TGF-β and in vivo phenotype may reflect activities of other ligands (e.g., activin), which can also signal through the Smad pathway.[185]

The bone morphogenetic protein 4 (BMP4), which also signals through the Smad pathway, has been shown to have an essential role in regulating hematopoietic development across different species.[185,213-215] BMP4 has been shown to modulate adult human HSC maintenance and proliferation in culture in a concentration-dependent manner[216] but does not induce significant proliferation of murine HSCs in vitro.[217] Studies by Bhardwaj et al[218] suggest an intersection between BMP4 and hedgehog signaling in the hematopoietic system. Hedgehog proteins, similar to BMPs, regulate the formation of the early mesoderm and specify several nonhematopoietic tissues during development.[219-222] In humans, there are three hedgehog proteins: Sonic hedgehog, Indian hedgehog, and Desert hedgehog.[218,223,224] Bhardwaj et al[218] reported that culture of human CB progenitor cells with Sonic hedgehog promoted the expansion of cells capable of multilineage repopulation in NOD/SCID mice. The addition of Noggin, a natural inhibitor of BMP4, blocked the effect of Sonic hedgehog on CB stem cell proliferation in culture, suggesting that BMP4 acts downstream of Sonic hedgehog in regulating human HSC growth.[218] Although these results suggest that hedgehog signaling regulates human HSC growth, it has also been shown that deletion of Smoothened, the downstream effector of Sonic hedgehog signaling, had no effect on HSC content or hematopoiesis in adult mice.[225-227] Similarly, pharmacologic inhibition of hedgehog signaling in adult mice had no effect on hematopoiesis.[227] Last, Gao et al[226] demonstrated that mice with MxCre-driven Smoothened activation displayed no expansion of the HSC pool in vivo. Taken together, these results provide conflicting results as to the role of hedgehog signaling and BMP4 in regulating HSC fate.

Although the role of BMP4 and hedgehog signaling in regulating adult hematopoiesis is not clear, the importance of Smad proteins in regulating HSC self-renewal has been unambiguously demonstrated.[103,185] Using an MxCre model, Smad4, the essential mediator of Smad pathway signaling, was shown to be essential for HSC self-renewal in vivo.[103] Interestingly, retroviral-mediated overexpression of Smad7, an inhibitor of the Smad pathway, also promoted HSC self-renewal in vivo.[228] Taken together, these results have been interpreted to indicate that Smad4 positively regulates HSC self-renewal independently from its role as a mediator of Smad pathway signaling.[185,229] This hypothesis is supported by evidence demonstrating that Smad proteins can activate Wnt signaling, which has been shown to promote HSC expansion.[185,187,229]

NOVEL GROWTH FACTORS FOR HEMATOPOIETIC STEM CELLS

Recently, several novel proteins and small molecules have been reported to promote potent expansion of murine or human HSCs in culture (Table 8-1).[87,230,231] Zhang et al[232] reported the discovery of the proteins, angiopoietin-like 2 (Angptl2) and Angptl3, in a fetal liver stromal cell line and demonstrated that the addition of Angptl2 or Angptl3 to cytokine cultures supported a 24- to 30-fold expansion of human BM cells capable of long-term repopulation in NOD/SCID mice. Subsequently, Zhang et al[233] demonstrated that the addition of Angptl5 and IGFBP2 to the combination of SCF, TPO, and FGF1 supported up to a 20-fold increase in human CB cells capable of 8-week engraftment in NOD/SCID mice. Of note, the receptor for Angptl proteins has not yet been cloned, so the mechanism through which Angptl proteins facilitate HSC expansion remains unknown.[232] Also, because the addition of Angptl 5 and IGFBP2 did not substantially increase total cell expansion compared with SCF, TPO, and FGF1 alone, it remains possible that treatment with Angptl proteins or IGFBP2 may enhance the homing of HSCs in immune-deficient transplant models.[233] Nonetheless, Angptl proteins represent attractive targets for translation into the clinic on the basis of the potency of their activity on human CB HSC expansion in preclinical models.

North et al[234] recently reported that prostaglandin E_2 (PGE_2) positively regulates HSC formation in the zebrafish model. These authors also demonstrated that short-term (1- to 2-hour) treatment of murine HSCs with PGE_2 produced a two- to threefold increase in donor cell repopulation in transplanted mice compared with mice transplanted with untreated cells.[234] Subsequently, Goessling et al[235] showed that PGE_2 modulates Wnt signaling via regulation of β-catenin degradation and PGE_2/Wnt activation regulated both hematopoietic regeneration in the zebrafish and long-term HSC repopulation in mice. Hoggatt et al[236] also showed that short-term exposure to PGE_2 promoted the enhanced homing and repopulation of human CB HSCs in immune-deficient mice and showed that this increased homing capacity may have been secondary to increased CXCR4 expression on PGE_2-treated CB HSCs. Ex vivo treatment with PGE_2was subsequently shown to increase human CB CFC content and engraftment capacity after transplant into immune-deficient mice, and PGE_2-treated BM cells were also found to provide more than 1 year of multilineage reconstitution in a non-human primate model.[237] Based on these encouraging results, a phase I clinical trial has been initiated in which 1 unmanipulated CB unit and the progeny of a second CB unit cultured with PGE_2 will be transplanted into adult patients after nonmyeloablative conditioning.[111]

Recently, screening strategies have been successfully used to identify novel growth factors for HSCs. Himburg et al identified pleiotrophin (PTN), a heparin binding growth factor, from a gene expression analysis of human brain-derived endothelial cells (ECs) that support

Table 8-1 Soluble Proteins and Small Molecules that Regulate Hematopoietic Stem Cell Self-Renewal

Growth Factor	Function in HSC Self-Renewal	Reference(s)*
Notch ligands	Sufficient, not necessary	176,177,181-183
Wnt proteins	Sufficient, ? necessary	187,189,193,194
BMPs	? Sufficient, Smad4 necessary	103
SCF	Necessary, not sufficient	230
TPO	Necessary, not sufficient	231
RAR-γ	Necessary	87
Ang-PTL	Sufficient	232,233
PGE_2	Sufficient	234,237
PTN	Sufficient, ? necessary	77,242
AhR antagonist	Sufficient	244

human HSC expansion in vitro.[238-241] Treatment of murine BM HSCs with PTN produced a 1-log expansion of long-term repopulating HSCs in culture, and systemic administration of PTN to irradiated mice caused a 20-fold increase in the recovery of BM LTC-ICs in vivo.[77] Mechanistically, PTN signaling caused the upregulation of PI3k/Akt signaling and Hes1 expression in HSCs, suggesting that activation of these signaling cascades may contribute to PTN-mediated HSC expansion.[77] Recently, these authors reported that mice lacking PTN ($PTN^{-/-}$ mice) had 11-fold less BM HSC content than $PTN^{+/+}$ mice.[242] Subsequently, it was reported that chimeric mice that had deletion of PTN in the BM microenvironment (WT;$PTN^{-/-}$ mice) contained increased LT-HSC content compared with WT;$PTN^{+/+}$ mice, as measured in tertiary and quaternary transplants.[243] Taken together, these results suggest that PTN is a potent mediator of BM HSC expansion and regeneration, but persistent PTN signaling may result in exhaustion of the most primitive HSC pool in vivo.[77,243] Further studies will be necessary to resolve these questions and define the potential therapeutic efficacy of PTN. Boitano et al[244] described a screening approach of more than 100,000 heterocyclic compounds for capacity to maintain human $CD34^+$ cells in 5-day culture. This yielded the discovery of a purine derivative (StemRegenin 1), which was shown to promote the expansion of human CB repopulating cells in vitro.[244] Three-week cultures of human CB $CD34^+$ cells with thrombopoietin, SCF, Flt-3 ligand, interleukin-6 (IL-6), and StemRegenin 1 promoted a 17-fold increase in SCID-repopulating cells compared with the progeny of cultures containing thrombopoietin, SCF, Flt-3 ligand, and IL-6 alone.[244] This purine derivative appears to mediate its effects via inhibition of the aryl hydrocarbon receptor. Aryl hydrocarbon receptors are expressed by HSCs, but the downstream signaling mechanism through which StemRegenin 1 mediates HSC expansion remains unknown.[244]

Methods for Hematopoietic Stem Cell Expansion in Clinical Testing

In addition to the novel preclinical methods to amplify HSCs described earlier, several different approaches to expand human CB HSCs have been tested in early clinical trials. Jaroscak et al[245] tested the combination of flt-3 ligand, a GM-CSF/IL-3 fusion protein, and erythropoietin in a continuous perfusion culture system as a means to expand human CB cells before transplant. Similarly, Shpall et al[246] tested the capacity of stem cell factor, granulocyte colony-stimulating factor (GCSF), and megakaryocyte growth and differentiation factor to expand human CB cells that were then transplanted in adult CB transplant recipients. An alternative approach to cytokine-based expansion of human CB cells was suggested by Peled et al,[247-249] who demonstrated a 159-fold increase in human $CD34^+$ cells in 7-week culture with a copper chelator, tetraethylenepentamine (TEPA), and cytokines. Subsequently, de Lima et al[250] reported the safety and feasibility of culturing human CB cells with TEPA and SCF, flt-3 ligand, IL-6, and thrombopoietin followed by transplantation into patients in a phase I/II clinical trial. Although each of these clinical trials has shown the feasibility of transplanting ex vivo–cultured CB cells, none demonstrated substantial acceleration in hematopoietic cell engraftment in CB transplant recipients compared to historical controls. However, the TEPA plus cytokine strategy is being tested further in a phase II/III study in several countries, including the United States.[111] In addition, de Lima et al recently described a dual CB transplant study in which patients were transplanted with 1 unmanipulated CB unit and the progeny of a second CB unit co-cultured for 14 days with either related donor mesenchymal stromal cells (MSCs) or third-party MSCs supplemented with SCF, Flt-3 ligand, GCSF, and thrombopoietin.[251] The authors reported a 40-fold expansion of $CD34^+$ progenitor cells and a median time to neutrophil engraftment of 15 days.[251] These results compare favorably with historical data regarding the engraftment kinetics of dual CB transplantation in adults and suggest the potential for ex vivo expansion methods to facilitate CB engraftment in adult patients.

HEMATOPOIETIC STEM CELL REGENERATION

Although much is now known about the intrinsic and extrinsic mechanisms that regulate adult HSC self-renewal and differentiation,[1,111,185] the process through which HSCs regenerate after injury (e.g., chemotherapy or radiation) remains less well understood. Successful delineation of the mechanisms that control HSC regeneration has significant therapeutic potential because a large proportion of patients with cancer receive myelosuppressive or myeloablative therapy during the course of their disease. Signaling through the BMP and Wnt signaling pathways has been shown to be necessary for hematopoietic regeneration to occur in zebrafish after sublethal irradiation.[252] These authors further demonstrated that Smad and TCF, the downstream effectors of BMP and Wnt signaling, respectively, couple with master regulators of myeloid and erythroid differentiation (C/EBPα and GATA1) to drive lineage-specific regeneration.[252] In a murine model of hematopoietic injury, Congdon et al[253] showed that Wnt10b expression is increased in BM stromal cells in response to irradiation, and Wnt signaling is activated in BM HSCs after irradiation. Interestingly, in a zebrafish model, activation of Wnt signaling during hematopoietic regeneration is modulated by PGE_2.[235] Wnt reporter activity was responsive to PGE_2 treatment, and the effect of Wnt8 toward enhancing hematopoietic recovery after sublethal irradiation was inhibited by administration of indomethacin, a PGE_2 antagonist.[235] Notch signaling has also been implicated in the regulation of hematopoietic regeneration after stem cell transplantation.[254] Deletion of Notch 2, but not Notch 1, was shown to delay myeloid reconstitution in mice after stem cell transplantation.[254] These data suggest that the BMP, Wnt, and Notch pathways are attractive mechanistic targets for strategies to augment hematopoietic regeneration after myelosuppressive therapy.

Additional signaling pathways have been implicated in regulating hematopoietic regeneration. Deletion of plasminogen (Plg), a fibrinolytic factor, was shown to prevent hematopoietic progenitor cell proliferation and recovery after fluorouracil (5FU)-induced myelosuppression in mice.[255] Conversely, administration of tissue plasminogen activator promoted hematopoietic progenitor cell proliferation and differentiation after myelosuppression, and this effect was dependent on matrix metallopeptidase 9–mediated release of c-kit ligand.[255] Similarly, Trowbridge et al[256] reported that mice that were heterozygous for Patched 1 ($Ptc1^{+/-}$), the receptor for hedgehog, displayed earlier recovery of hematopoiesis after 5FU-induced myelosuppression compared with littermate $Ptc1^{+/+}$ mice. Hedgehog binding blocks Patched 1–mediated inhibition of Smoothened, thereby promoting downstream hedgehog signaling. Therefore, $Ptc1^{+/-}$ mice have enhanced hedgehog signaling, and these results implicate hedgehog signaling as positively regulating short-term hematopoietic regeneration after injury. However, this acceleration in hematopoietic recovery in $Ptc1^{+/-}$ mice occurred at the expense of LT-HSCs, which were exhausted in these mice.[256] Genetic studies have similarly demonstrated that deletion of SHIP (SH2-containing inositol phosphatase, $SHIP^{-/-}$ mice) is associated with increased loss of HSCs in mice after 5FU exposure compared with $SHIP^{+/+}$ mice.[257] In a similar model of 5FU-mediated myelosuppression, Nemeth et al[258] reported that mice deficient in the high-mobility group 3 (HMGB3) DNA binding protein exhibited more rapid recovery of phenotypic HSCs compared with wild-type mice. The enhanced recovery of the stem/progenitor pool in HMGB3-deficient mice was associated with activation of Wnt signaling, suggesting that activation of the Wnt pathway may accelerate HSC recovery after myelosuppression. Of note, overexpression of the signal transducer and activator of transcription 3 (STAT3) in HSCs increases their regenerative capacity after transplant into lethally irradiated mice.[259] In this study, it was not determined whether alteration in STAT3 expression affected HSC regeneration after myelosuppression (e.g., 5FU or irradiation).[259]

At the cellular level, increasing evidence suggests an important role for BM ECs in promoting hematopoietic regeneration after myelotoxic stress.[260-263] Genetic deletion or antibody-based inhibition of vascular endothelial growth factor receptor 2 (VEGFR2), which is expressed by sinusoidal BM ECs, was shown to delay both BM

vascular and hematopoietic recovery after total-body irradiation (TBI).[260] Systemic infusion of syngeneic or allogeneic ECs has also been shown to significantly accelerate the recovery of both the HSC pool and overall hematopoiesis in mice after high-dose TBI.[261,264] Salter et al[261] and Butler et al[265] further demonstrated that hematopoietic regeneration after irradiation is dependent on vascular endothelial (VE)-cadherin–mediated vascular reorganization because administration of a neutralizing anti VE-cadherin antibody caused significant delay in hematologic recovery in mice after TBI. The mechanisms through which BM ECs regulate HSC regeneration in vivo remain unclear, but it was recently shown that systemic administration of PTN, a heparin binding protein that is secreted by both BM and brain ECs, causes a rapid increase in recovery of the HSC pool in mice after high-dose TBI.[77] Taken together, these studies suggest that the BM vascular niche may be an important reservoir for the discovery of growth factors and membrane-bound proteins that mediate HSC regeneration.

Lastly, the effect of age on the capacity for HSCs to regenerate after myelosuppressive challenge remains an important question.[266] Not surprisingly, older mice with defects in DNA damage repair mechanisms (nucleotide excision repair, nonhomologous end-joining) and telomere maintenance displayed severe defects in their capacity to reconstitute hematopoiesis after transplantation into lethally irradiated recipient mice compared with age-matched control subjects that retained the DNA repair and telomerase genes.[267] Therefore, therapeutic targeting to accentuate these DNA repair mechanisms may facilitate the recovery of the functional HSC pool after myelosuppression and may lessen the oncogenic risk incurred via repeated exposure to DNA-damaging therapies (e.g., alkylators and irradiation).[267]

GENERATING HEMATOPOIETIC STEM CELLS FROM EMBRYONIC STEM CELLS AND INDUCED PLURIPOTENT STEM CELLS

After the successful isolation of ESCs from both mice and humans, it has been shown that ESCs can be induced to differentiate into tissues representative of all three germ layers, raising the potential for regenerative therapy.[268,269] There has been particular optimism that human HSCs could be generated from ESCs or iPS cells.[268] Indeed, initial studies demonstrated that murine hematopoietic progenitor cells could be generated from murine ESCs in vitro.[46] However, subsequent studies indicated that without further genetic manipulation, hematopoietic progenitor cells generated from murine ESCs lacked complete in vivo multilineage repopulating potential.[268,270,271] To overcome this obstacle, investigators leveraged knowledge from studies of hematopoietic development in the zebrafish and in mice to demonstrate the feasibility of generating HSCs with in vivo repopulating capacity from ESCs and iPS cells.[127,268,272] Cdx and Hox genes were shown to be essential for embryonic blood formation in the zebrafish,[127,268,272] and Cdx gene–deficient murine ESCs displayed impaired hematopoietic potential that could be rescued via ectopic expression of Cdx4.[273] In a complementary study, it was shown that the ectopic expression of Cdx4 in murine ESCs promotes hematopoietic specification and, coupled with HoxB4 expression, increases the multilineage hematopoietic repopulating potential of ESC-derived HSCs as measured in lethally irradiated recipient mice.[274] Subsequently, Lengerke et al[275] demonstrated that hematopoietic specification of murine ESCs is directed by BMP4, which activates Wnt3a and upregulates both Cdx and Hox genes.

With the successful generation of iPS cells from somatic cells via the retroviral introduction of OCT4, SOX2, c-Myc, and KLF4 transcription factors[131-133,135] and the subsequent demonstration that human iPS cells can be generated via coupling of the histone deacetylase inhibitor, valproic acid, with retroviral expression of OCT4 and SOX2,[276] scientists are now poised to generate human HSCs with long-term repopulating capacity from iPS cells.[268,274] Lengerke et al[268] reported that fibroblast-derived human iPS cells can be induced to generate hematopoietic progenitor cells via culture with BMP4 and hematopoietic cytokines. In this study, iPS-derived hematopoietic cells were confirmed via cell surface expression of CD34 and CD45, colony-forming cell content, and expression of hematopoietic-specific genes *(SCL, GATA2)*.[268] However, the authors did not describe whether these human iPS-derived hematopoietic progenitors retained multilineage in vivo repopulating capacity.[268] Tolar et al[277] subsequently demonstrated that human iPS cells could be generated from both keratinocytes and mesenchymal stromal cells from patients with mucopolysaccharidosis type I (Hurler syndrome), and these cells could be induced to develop a hematopoietic phenotype and gene expression profile after culture with BMP4 and hematopoietic cytokines. Taken together, these studies suggest that the generation of HSCs from human iPS cells is at least feasible and provide a conceptual framework for how iPS-derived hematopoietic cells could be used for the autologous correction of hematopoietic disorders.

CHAPTER 9

HEMATOPOIETIC MICROENVIRONMENT

Lev Silberstein and David Scadden

EVOLUTION OF THE NICHE CONCEPT

In 1868, Ernest Neumann first suggested that blood cells are being replenished throughout postnatal life, and this proposal led to the attempts to localize the place of hematopoiesis.[1] His proposal that blood cell production takes place in the bone marrow (BM) was experimentally validated by selective lead shielding of limbs in irradiated animals almost a century later.[2] Notably, these and other studies showed that differentiation pathways of immature blood cells are determined by their location and are different between the spleen and the BM.[3] Based on this difference between BM and spleen, Schofield first proposed that there is a specialized place or niche where stem cells reside and are governed. He succinctly proposed in 1978 that "stem cell is seen in association with other cells which determine its behavior."[4] Stem cells reside in a defined microanatomic site and respond to local and systemic signals.

Trentin further clarified how different sites affected hematopoietic stem cell (HSC) differentiation.[5] Although both spleen and marrow support multiple cell lineages (erythropoietic and granulocytopoietic, for example), the ratios of differentiating cells were different—spleen favored erythropoiesis, but BM predominantly supported granulopoiesis. This controlling influence of the "stroma" was further illustrated by implanting BM stroma into the spleen and showing that hematopoietic cells abruptly changed showed that abrupt change from erythropoiesis to granulopoiesis at the spleen–BM demarcation. These observations suggest that immature differentiating progenitors require interactions with specific other cell types in a defined *micro*environment.

Niches are not static, however. Although HSCs migrate in early development and throughout adult life, so do the niches that support their dynamic ability change in function and in number. For example, the niche has to have the ability to respond to stress signals from the sympathetic nervous system or granulocyte colony-stimulating factor (G-CSF) and control the exit of hematopoietic cells from the bone marrow to the peripheral blood.[6] Moreover, the niches can be created anew in the context of disease and development. Therefore, a proper functioning of the hematopoietic system can be achieved through the ability of the niche not only to maintain the resident pools of functional cells but also respond to physiologic need.

This chapter reviews the current knowledge of the hematopoietic microenvironment during development and in postnatal life, with a particular focus on recent in vivo data. The chapter also reviews the evidence for the contribution of the microenvironment toward development and maintenance of leukemia and myelodysplasia and the opportunities for therapeutic manipulation of the niche in the treatment of these disorders. For the related topics on stem cell mobilization, hematopoietic cytokines and the role of microenvironment in lymphoid malignancies, plasma cell disorders, and myeloproliferative conditions, readers are referred to other chapters of this book.

HEMATOPOIEITIC MICROENVIRONMENT DURING DEVELOPMENT

In mammals, hematopoiesis during development takes place in distinct extra-embryonic and embryonic sites. Sequentially, it moves from the yolk sac to the aorta-gonad-mesonephros (AGM) region, fetal liver, placenta, and bone marrow (for details, see Chapter 8).

The first definitive adult HSCs emerge from the floor of the dorsal aorta, more precisely from AGM region in midgestation mouse embryo, and the HSC clusters appear in close association with the aortic endothelium.[7] Recent reports indicate that phenotypically defined HSCs (Sca1+ c-kit + CD41+) arise directly from ventral aortic endothelial cells and that fluid shear stress may be important for this process.[8,9] Although direct cellular interactions during hematopoietic stem cells (HSCs) emergence in the embryo remain to be dissected, bone morphogenetic protein 4 (BMP4), fibroblast growth factor (FGF), transforming growth factor (TGF), and vascular endothelial growth factor (VEGF)-Flk1 signaling pathways are involved in early mouse hematopoiesis.[10,11]

Recently, placenta has been identified as a hematopoietic organ during development.[12] Placenta is known to produce hormones that influence vascularization and therefore may affect blood cell production because hematopoiesis and vasculogenesis are tightly coupled.[13] The hematopoiesis-promoting factors may be either produced by the placental trophoblast cells or enter via maternal circulation. Hematopoietic progenitors appear in the placenta at E9, but their number declines by E13. The cells and local factors providing placental hematopoietic support are currently unknown, but mesenchymal/stromal cells have been suggested as candidates. Placental microenvironment is thought to be geared toward supporting the expansion or maturation of HSCs without their concomitant differentiation.

In the fetal liver, the HSCs are first detected on day 9 of mouse embryonic development, and large expansion of the HSCs occurs between days 12 and 15 before migration to the bone on day 18. Stromal cell lines obtained from the fetal liver are able to support primitive hematopoietic cells in ex vivo cultures.[14,15] Some of these cells (termed *myelosupportive stroma*) are able to differentiate in vitro into mesenchymal components (osteoblasts, chondrocytes, and adipocytes).[10] Although the nature of fetal liver cells participating in the HSC niche remains enigmatic, recent studies point to a nonhematopoietic hepatic population that express Dlk-1, a member of delta-like family of cell surface transmembrane proteins, and stem cell factor, and can be prospectively isolated based on the expression of these molecules.[16] These cells express angiopoietin ligand 3 and CXCL12, and in combination with stem cell factor, thrombopoietin, FGF1 and FGF2, and either angiopoietin ligand 2 or 3 are able to produce more than 30 expansion of the murine HSCs in culture.

Despite the differences in the hematopoietic microenvironment between the sites of fetal and adult hematopoiesis, the

key components of the molecular milieu are likely to be shared, as evidenced by successful (although limited) engraftment of HSCs across developmental barriers. For example, AGM- or fetal liver–derived HSCs are able to engraft in the adult BM. Notably, they have a competitive advantage over their BM-derived counterparts, with the long-term repopulating ability exceeding that of the BM by five-fold.[17] Vice versa, BM HSCs engraft in fetal liver when transplanted in utero, although at low efficiency (<5% for the whole BM and 0.43% for highly enriched HSCs), which may be partly attributable to the absence of pretransplant conditioning.[18]

Multilineage hematopoiesis during development occurs largely by the virtue of sequential HSC migration from the AGM region to the fetal liver and the BM, as opposed to de novo HSC generation.[19,20] Failure of migration to the "next niche," as exemplified by the targeted disruption of the guanine-nucleotide–binding protein stimulatory α-subunit (GS-α), calcium-sensing receptor, or CXCL12/CXCR4 axis (discussed in detail in Chapter 11 on HSC migration) leads to severe impairment in hematopoiesis.[21-23] This suggests even in the absence of cell-intrinsic HSC defects, proper progression of blood cell production throughout developmental critically depends on the ability of the HSC to sequentially move to the appropriate microenvironmental compartments.

ADULT BONE MARROW MICROENVIRONMENT

Hematopoietic Stem Cell Niches

In mammals, BM is a major site of hematopoiesis throughout life. Over the recent years, animal studies revealed tremendous complexity in cellular and molecular organization of the HSC BM niche (Fig. 9-1). In evaluating the results of these studies, it is important to be aware of formidable experimental challenges in the field, as outlined below. These account for inherent limitations to our knowledge and often generate considerable controversies.

First, the HSC niche is a dynamic entity. However, the majority of current experimental approaches are not suitable for adequately capturing cell interactions within the niche in real time. This problem is being gradually circumvented by in vivo imaging studies (see below), although they are limited to providing a largely descriptive picture of the niche.

Second, current studies are mainly focused on the "conditioned" niches, usually by total-body irradiation (TBI), in a transplant model. The HSC niches can be identified in vivo only spatially (i.e., on the basis of co-localization between a nonhematopoietic "niche cell" and an HSC). However, endogenous HSCs are extremely rare (1 : 10,[5]

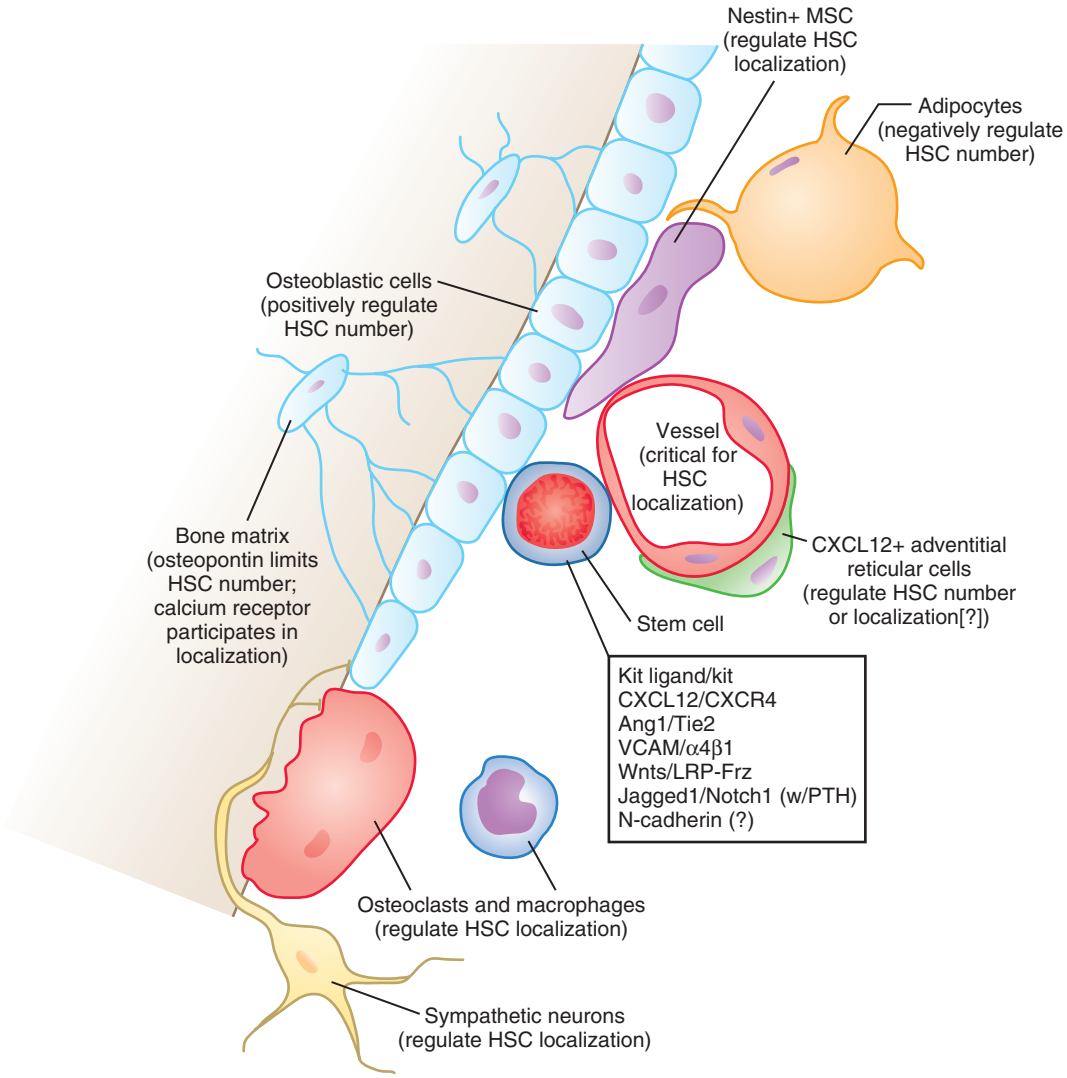

Figure 9-1 BONE MARROW HEMATOPOIETIC NICHE COMPONENTS TO DATE. *Ang1,* Angiopoietin-like 1; *HSC,* hematopoietic stem cell; *MSC,* mesenchymal stem cell.

nucleated cells)[24] and lack reliable markers for visualization in normal tissues with the same specificity as they can be isolated from the BM by fluorescence-activated cell sorting (FACS). Therefore, the vast majority of studies that focused on the HSC niche do so by injecting highly purified FACS-sorted HSCs into an animal recipient. This approach has the advantage of standardized and homogeneous input HSC and progenitor population but involves conditioning of the recipient niche, usually by TBI. Irradiation has a profound effect on the BM microenvironment.

For example, irradiation largely destroys the vascular compartment[25] and is also able to make the niche more "receptive" to HSCs; post-irradiation increase of CXCL12, a major HSC chemoattractant, is well documented.[26] In addition, irradiation increases the number of available niches, which is limited under physiologic conditions; transplantation of the BM into nonconditioned recipient in both neonatal[27] and adult mice results in a very low level of chimerism (0.1.%), suggesting that "empty" niches that are made vacant by circulating HSCs can be saturated. Interestingly, these niches can be "emptied" by using a cytotoxic antibody against HSC surface molecule c-kit, and the level of engraftment increases proportionally to the number of transplanted HSCs.[28] Thus, "conditioned" niches are likely to be different from those that exist under physiologic conditions, both in quality and number, and the effect of these factors on experimental readout is unknown.

Third, an important caveat inherent to those experimental systems, which use genetic tools to either increase or delete a target cell population within the niche, is that these manipulations often produce a compensatory response from surrounding cells or are associated with deletion of developmentally related downstream cell populations. Therefore, it is often difficult to conclusively attribute a phenotypic change observed in the hematopoietic compartment to a specific cell population.

Finally, studies of hematopoietic microenvironment largely rely on the use of rodent models. However, major differences exist between rodents and humans with regard to location of hematopoiesis. For example, in rodents, all bones support hematopoiesis, and the long bones (femurs and tibias) are the sites in which the BM hematopoiesis is studied. In humans, the axial skeleton (the cranium, sternum, ribs, vertebra, and ilium) is the major site of blood cell production, and the red marrow in the long bones is replaced by yellow (hematopoietically inactive) marrow between 5 and 7 years of age, with the exception of the proximal regions of the long bones.[29] Also, whereas in rodents, the spleen remains a site of active hematopoiesis throughout life, in humans, it does not support hematopoiesis after birth except for the times of hematopoietic stress or in pathologic conditions such as idiopathic myelofibrosis.[30] Because the experimental data presented in this section have been obtained in mice, their applicability to humans remains to be established.

Here, we will review the current knowledge of cellular components of the HSC niche, the biochemical pathways involved in extrinsic control of HSC self-renewal, and systemic factors such as neural input or oxygen tension which regulate the niche at the level of an organism.

Osteolineage Cells

Osteolineage cells (OLCs) are a heterogeneous population of mesenchymal cells that line the endosteal surfaces of flat and trabeculated bones at the interface between the bone and the BM and become embedded within the bone matrix upon terminal differentiation. OLCs are thought to originate from mesenchymal stem cells (MSCs) and gradually progress from the early immature progenitors that express OLC-specific transcription factors Runx2 and osterix to mature osteoblasts expressing extracellular matrix protein osteocalcin and eventually to osteocytes.[31]

The endosteal surface has long been considered the zone in which HSCs are preferentially located.[32] Failure to engage the endosteal niche, as seen in animals with homozygous deletion of Ca-sensing receptor, leads to a marked reduction of the HSC pool,[23] and augmented lodgement at the endosteal surface because of pharmacologic stimulation of the same receptor leads to enhanced HSC engraftment.[33] It therefore seems intuitive that OLCs influence hematopoiesis. Indeed, both mouse and human OLCs have been shown to produce hematopoietic growth factors (GCSF, granulocyte-macrophage colony-stimulating factor [GM-CSF], and others) and stimulate proliferation of hematopoietic cells in vitro.[34,35] Several lines of recent in vivo evidence also argue in favor of a functional role of the OLCs in the HSC niche.

1. *Activation of OLCs increases HSC pool size.* Two simultaneously published studies used genetically modified OLCs to show that increase in number of activated OLCs leads to a corresponding increase in the number of long-term HSCs. In one, the OLCs and other cells in the microenvironment harbored a deletion in the bone morphogenic protein receptor 1A, which resulted in ectopic formation of trabecular bone area and correlated with a twofold increase in the number of HSCs, both by immunophenotypic and functional assays.[36] In the other study, the OLCs specifically expressed a constitutively activated form of the parathyroid hormone–related peptide receptor (PPR).[37] Similar to the other model, these animals had an increased trabecular bone area and an elevated number of trabecular osteoblasts that expressed the Notch ligand Jagged 1 and displayed a twofold increase in HSCs. This effect was abolished in the absence of osteopontin, an extracellular matrix protein produced by the OLCs, thus shown to negatively control the HSC pool size.[38] Importantly, exogenous administration of PTH after myeloablative BM transplantation in PPR animals significantly improved survival and increased BM cellularity compared with the control group, highlighting the potential for therapeutic manipulation of the niche.[39]

 The above studies suggested that trabecular OLCs are particularly important for the HSC niche function. This notion was strengthened by a recent observation that after irradiation, there are areas of expansion of the trabecular OLC population, which serve as sites of hematopoietic engraftment.[40] OLCs in the epiphyses of the long bones showed no visible proliferative response and look similar to non-irradiated controls. Remarkably, 10 days after irradiation and transplantation, the above changes in the OLC compartment were no longer detectable, underscoring the transient and dynamic nature of the OLC niche in post-irradiation BM.
2. *Depletion of the OLCs reduces hematopoiesis.* Using a suicide gene strategy in which thymidine kinase was driven by the collagen 2.3 promoter, the OLCs were specifically deleted after administration of gancyclovir.[41] This led to a marked reduction in the BM cellularity and appearance of hematopoiesis in the extramedullary sites, arguing against a nonspecific toxicity of ganciclovir. Importantly, after the treatment was discontinued, the OLCs regenerated and the BM hematopoiesis returned, suggesting a specific role of the OLCs within hematopoietic niche. The effect of the OLCs on hematopoiesis was restricted to a relatively immature cell population because depletion of a more mature (osteocalcin-positive) OLC using the same thymidine kinase/ganciclovir strategy had no appreciable effect on the BM cellularity despite development of osteoporosis.[42] Thus, the HSC-supporting ability is likely to be restricted to a specific OLC fraction. Therefore, it is not surprising that some studies failed to detect the correlation between OLC deletion and expansion and the HSC number because the "effector" OLC population may not have been affected.[43,44]
3. *OLC may participate in HSC quiescence and mobilization.* Studies of stem cell niches in other model systems (e.g., *Drosophila* testis) have shown that interaction with the niche is necessary to induce stem cell quiescence and prevent exhaustion through differentiation or excessive proliferation.[45] As already mentioned, a similar niche function for the HSC niche was proposed by Schofield in his original conception of the niche and found experimental support in several in vivo studies aimed at identifying the

molecular mediators of HSC-OLC cross-talk. In the experiments using OLC-specific expression of the paninhibitor of canonical Wnt signaling Dickkopf1 (Dkk1), HSCs were found to have increased cycling and progressive loss of regenerative function.[46] These results contradict the work with pharmacologic doses of Wnt3a in vitro,[47] suggesting the importance of dose and cell context for the Wnt effects. Another OLC-derived inhibitor of HSC proliferation is angiopoietin 1, which interacts with receptor thyrosine kinase Tie-2 to induce HSC quiescence, and this interaction protects HSCs from myelosuppressive stress.[48] Similarly, OLC-secreted thrombopoietin increases the number of quiescent HSCs by acting through its receptor c-mpl, although when administered exogenously, its effect is transient.[49a] Given that both angiopoietin 1 and thrombopoietin can be produced by other cell types, these studies provide only indirect evidence for the OLC involvement in the HSC niche.

OLCs also participate in regulating OSC localization. HSCs egress into blood and return to the BM, a process that forms the basis for clinical peripheral blood stem cell collection for transplantation. After administration of GCSF, the OLCs in the trabecular bone adapt a flattened morphology with short projections, associated with HSC egress from the niche.[6] Also, in studies in which mature OLCs were deleted from bone, GCSF was not able to induce HSC mobilization into the blood.[49b] OLCs therefore have a role in regulation of HSC traffic.

4. *In vivo imaging shows that transplanted HSCs are located adjacent to osteolineage and perivascular cells.* Until recently, our knowledge of HSC microenvironment came from studies that used immunostaining to visualize engrafting HSCs and surrounding cells. However, histologic sections are unable to represent the three-dimensional structure of the BM, making it difficult to capture the spatial relationship between HSCs and other niche components. Moreover, they only provide a static assessment of cell interactions and do not account for the changes that occur within the HSC niche over time.

 The advent of two-photon confocal microscopy enables examination of intact tissue at the depth of multiple cell layers (150-μm), and application of this technology to live animal imaging allowed microanatomic analysis of the HSC–OLC interaction in real time[25] (Fig. 9-2). Currently, in vivo imaging is limited to calvarial BM, an area in the mouse skull where the bone is very thin, thus permitting penetration of the laser beam into the BM cavity. Using this technique and simultaneous multicolor fluorescent labeling of OLCs, HSCs, and the vasculature, studies showed that in irradiated recipients, transplanted HSCs home closest to the endosteal surface and individual OLCs compared with more differentiated progenitors, and are "anchored" to their niches at least through 72 hours. Importantly, the endosteal location of transplanted HSCs was observed in animals in which no preconditioning with radiation or chemotherapy was required. Similar results were observed in studies that used comparable techniques to visualize HSC–OLC interactions in the long bones, although performing these experiments in live animals remains a challenge.[50] Although descriptive in nature, imaging studies complement the results of molecular and genetic experiments by bridging the functional role of the OLCs in the niche and their intimate microanatomic relationship with HSCs.

Endothelial Cells

Endothelial cells are known to secrete hematopoietic cytokines and express several adhesion molecules such as E-selectin, P-selectin, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1),[51,52] raising the possibility of their involvement in the HSC niche. The existence of vascular niche for the HSCs has been suggested by in vivo imaging studies showing early homing of transplanted BM progenitors to specific subdomains of the vascular tree,[53] as well as by histologic assessment of the BM using CD150 antibody when HSCs were found to be in a close proximity to the BM sinusoids.[24] In vivo evidence delineating the role of vascular endothelium in HSC homeostasis is sparse, and it is therefore possible that close association of HSCs with blood vessels simply reflects their "transit" to and from the marrow as opposed to being indicative of functional interaction. However, observations that selected activation of Akt 1 in endothelial cells promotes expansion of long-term HSC number in vivo suggests that endothelial cells may be involved in modulating the balance between HSC quiescence, self-renewal, and differentiation.[54] Given that OLCs are perivascular,[55] any microanatomic distinction between the vascular and "osteoblastic" niche seems artificial, although it is possible that both cell types make functionally distinct contributions toward HSC homeostasis.

Adipocytes

An observation that adipocyte-rich vertebrae in mice contained significantly fewer cycling HSCs compared with adipocyte-poor thoracic vertebrae led to discovery of their role in HSC regulation.[56] In a genetic mouse model of lipoatrophy (i.e., a condition with reduced adipocyte number), posttransplant hematopoietic recovery was accelerated, although a concomitant increase in trabecular bone could have contributed to this result.

Osteoclasts

Osteoclasts are BM-derived cells that are located in close proximity to stem cell–rich endosteum and play a critical role in bone remodeling. During stress and GCSF-induced mobilization, the activity of the osteoclasts increases and is accompanied by secretion of proteolytic enzymes and reduction in the endosteal niche components, as

evidenced by downregulation of the osteopontin expression by the OLCs.[57] Conversely, inhibition of the osteoclasts leads to reduced HSC and progenitor egress.

Nestin-Positive Cells

The BM has long been known as a home for two stem cells—skeletal and hematopoietic. Skeletal stem cells—more commonly known as MSCs—are located in the perisinusoidal space. They are bona fide stem cells because they possess self-renewal capacity and an ability to differentiate into multiple skeletal or stromal tissues—bone, cartilage, and fat.[58] In mice, these cells can be identified through the expression of green fluorescent protein (GFP) under control of the regulatory elements of the intermediate filament protein nestin.[59] Nestin-positive cells receive innervation from sympathetic nervous system and are located in close proximity to endogenous and transplanted HSCs. Nestin-positive cells express the genes associated with HSC retention in the niche (Cxcl12, kit-ligand, and angiopoietin 1), which are downregulated upon GCSF mobilization. Selective deletion of Nestin-positive cells in mice resulted in 50% reduction in the number of long-term HSCs and their relocation to the spleen, although it is not clear whether this effect was mediated directly by Nestin-positive cells or through their more differentiated downstream progeny.

CXCL12-Abundant Reticular Cells

CXCL12 (also known as stromal-derived factor 1) is a major chemokine responsible for HSC trafficking to the BM. CXCL12-abundant reticular cells were identified in a mouse model in which GFP was driven by CXCL12 promoter.[60] Similar to the other components of the niche, CXCL12-abundant reticular (CAR) cells are found in a close proximity to HSCs. It is likely that they are genetically and phenotypically related to Nestin-positive cells because their ablation also severely impaired adipogenic and osteogenic differentiation of nonhematopoietic BM cells in addition to reducing the number of HSCs and increasing HSC quiescence. The effect of deletion was not limited to HSCs but also affected mature lineages, such as lymphoid cells (see below).

Bone Marrow Macrophages

During experiments investigating the mechanisms of GCSF-induced HSC mobilization, it was noted that in addition to previously reported reduction in the endosteal OLCs, BM macrophages were also decreased in number. In vivo depletion of this cell population by clodronate administration produced the same result. It therefore appears that macrophages play a critical role in supporting the OLC niche compartment. A similar role for the macrophages, but with regard to supporting Nestin-positive MSCs, has been suggested by another study that used clodronate-mediated macrophage ablation.[61,62] Again, this resulted in HSC egress from the BM, perhaps through the effect on Nestin-positive cells, which showed a marked downregulation of genes responsible for HSC retention in the niche (see earlier discussion). Thus, macrophages appear to function at a level of regulation upstream of OLCs and Nestin-positive cells.

EXTRINSIC REGULATION OF THE HEMATOPOIETIC STEM CELL NICHE

Innervation

Sensory and autonomic innervation of the BM is critical for its ability to respond to hematopoietic stress. As mentioned above, increase in sympathetic tone promotes HSC mobilization and down-regulates the components of the endosteal niche, mainly through the activation of β_2-adrenergic receptor.[6] Nestin-positive cells express both β_2 and β_3 receptors and act as another mediator between sympathetic signaling and HSCs, again facilitating egress from the BM.[59] In a mouse model of streptozocin-induced diabetes, diabetic autonomic dysfunction was shown to disrupt this regulatory circuit, alter the function of Nestin-positive cells, and lead to impaired GCSF-induced HSC mobilization, providing a biologic explanation for a higher frequency of peripheral blood stem cell mobilization failure in diabetic patients.[49b] The sympathetic nervous system is also involved in regulation of HSC egress from the BM as governed by circadian rhythms, a remarkable discovery based on a chance observation that continuous exposure to light (because of a broken light switch in the animal house) significantly altered the number of HSCs mobilized after GCSF administration.[63] Thus, niche innervation is essential for relaying and integrating extrinsic signals, and acts as a responsive and finely tuned tool, which regulates HSC traffic between peripheral blood and the BM.

Hypoxia

Several studies using the intracellular hypoxic marker pimonidazole have provided indirect evidence that the HSC niche is hypoxic.[64,65] Hypoxia is associated with upregulation of stromal cell–derived factor 1 (SDF-1) expression in the endosteal region and HSC traffic to the BM; in contrast, hyperbaric oxygen (exposure to 100% oxygen under increased atmospheric pressure) mobilizes HSC and progenitors away from the BM.[66,67]

Hypoxic responses in the HSCs are mediated through a family of hypoxia-inducible factors (HIFs). The best studied species of HIFs is HIF1-α, which induces SDF-1 expression and directs metabolic circuits within HSCs toward anaerobic metabolism.[68] HIF1-α also stimulates secretion of VEGF, thereby promoting bone formation and angiogenesis.[69]

What is a physiologic role of hypoxia? Firstly, hypoxia is believed to protect HSCs in the niche from oxidative stress.[70] Indeed, HSCs within the niche contain a lower level of reactive oxygen species. Moreover, it appears that hypoxic conditions are indeed beneficial for the HSC function because culturing human BM HSCs under lower oxygen tension leads to increase in their ability to engraft and repopulate nonobese diabetic/severe combined immune deficient (NOD/SCI) mice.[71] Finally, hypoxia may also protect the HSC pool from exhaustion by promoting cell cycle quiescence.[65] Therefore, manipulating hypoxia within the niche may serve as a powerful strategy to increase the number of self-renewing HSCs or shield them from cytotoxic stress by inducing quiescence.

These observations are in an apparent contradiction with the data suggesting that the HSC niche at the endosteal surface is perivascular and should in theory be highly oxygenated. Whether capillary flow is particularly slow in the sinusoidal networks of the BM vessels, the niche endothelium is highly specialized and allows oxygen diffusion at a very low rate, or BM vasculature has a low baseline level of oxygen is a subject of ongoing investigation.

LYMPHOID NICHES

Bone marrow is the site of *B-cell lymphopoiesis*. Several cell types involved in the HSC niche also participate in formation of the lymphoid niches. Interestingly, B-cell niche counterparts are determined by the maturation stage—whereas OLCs, osteoclasts, and CAR cells are necessary for the less mature stages of development, interleukin-7 (IL-7) secreting cells and sinusoidal endothelial cells are important for more differentiated cells.[72-74] These observations come from targeted deletion of each supporting cell population using genetic means and analyzing the effect on B-cell homeostasis. For example, deletion of the OLCs leads to a considerable decrease in pre-pro and pro-B cells. This process appears to be mediated by the heterotrimeric G protein α subunit because its deletion in

the OLCs leads to 60% decrease in the percentage of B-cell precursors in the BM.[75] A similar phenotype is seen upon deletion of CAR cells.[74]

Naïve recirculating B and T cells are located in the perisinusoidal space and co-localize with dendritic cells, which are thought to deliver supportive signals, because as their deletion leads to significant decrease in B-cell number and reduction in IgM production after immunization.[76,77]

Plasma cells are the product of terminal differentiation of B cells after antigen exposure. In vitro and in vivo studies showed that plasma cells receive multiple extrinsic survival signals, including CXCL12, IL-6, BAFF (B-cell activating factor of the TNF family), and APRIL (a proliferation-inducing ligand), which may account for their longevity.[78] Mice deficient in CXCR4 displayed impaired homing of plasmablasts, illustrating the involvement of CXCL12–CXCR4 axis in plasma cell trafficking.[79] Eosinophil- and megakaryocyte-derived APRIL and BAFF appear to regulate the number of plasma cells, which is greatly reduced upon eosinophil or megakaryocyte deletion.[80]

The majority of long-lived *memory T cells* reside in the BM and appear to require a close contact with IL-7 secreting stromal cells to ensure that they remain quiescent in the absence of antigen stimulation.[74] The BM also contains a large proportion of *regulatory T cells,* which have recently been found to exclusively protect HSCs and early progenitors from rejection after allogeneic transplantation, arguing that the endosteal surface act as an immune privileged site.[81]

ERYTHROID NICHES

Erythroblastic islands were first described by a French hematologist Marcel Bessis more than 50 years ago and consist of developing erythroblasts surrounding a central macrophage.[82] They are present in the BM, fetal liver, and the spleen and in in vitro long-term BM cultures. The number of erythroblasts per island ranges from 10 cells observed in sections of rat femur to 5 to 30 erythroblasts seen in human BM. Some islands are located adjacent to the BM sinusoids, and the others are scattered throughout the BM cavity. Within erythroid islands, the macrophage functions as a "nurse cell" providing iron to the developing erythroblasts and phagocytosing the extruded nuclei at the end of erythroid differentiation.

Adhesion between maturing erythroblasts and central macrophage is mediated by several molecules, including erythroblast macrophage protein (Emp via homophilic binding),[83] $\alpha 4\beta 1$ integrin (VCAM-1),[84] and αv integrin (ICAM-4)[85]; antibody-mediated blockade each of these molecule results in disruption of the islands. The most striking effect is seen with the blockade of Emp, which causes significant increase in proliferation, maturation, and apoptosis of maturing erythroblasts in vitro. Of note, Emp-null fetuses die in utero from severe anemia.[83]

In addition to interaction within macrophages, maturing erythroblasts adhere to extracellular matrix proteins, fibronectin, and laminin for the maturation to proceed. Fibronectin protects erythroblasts from apoptosis, partly through anti-apoptotic bcl-xL, and laminin is thought to localize reticulocytes to sinusoids as the initial step before their release into circulation.[86,87]

MEGAKARYOCYTIC NICHES

Megakaryocytes localize to BM endothelial cells in vivo and release platelets into the marrow intravascular–sinusoidal space or the lung capillaries. Although CXCL12 induces platelet production by megakaryocytes if preceded by migration through endothelial cells, this is not observed in the absence of endothelial cells, suggesting that megakaryocyte interaction with specific molecules present on the endothelial cells is necessary for thrombopoiesis.[88] FGF4 and CXCL12 enhance the interaction of megakaryocytes with endothelial cells and restore thrombopoiesis in mice deficient in thrombopoietin or its receptor c-mpl. Thus, chemokine-mediated localization of megakaryocytes within a specific vascular microenvironment is necessary for their maturation and platelet production.

HUMAN BONE MARROW MICROENVIRONMENT

Because direct mechanistic studies of human BM microenvironment cannot be undertaken, the bulk of our knowledge comes from experiments in xenotransplantation models.[89] These initially involved fetal sheep and heavily irradiated or nude mice as recipients, but only very low level of human hematopoietic engraftment was observed. The discovery of SCID mice led to development of two powerful models. The first, known as SCID-hu mouse, was generated by engrafting human thymus and fetal liver. This model was most informative for the study of human lymphoid development and is still used for testing novel HIV drugs.[90] The second model, hu-SRC (for SCID-repopulating cell), through the pioneering work of John Dick and colleagues,[91] enabled investigation of human HSC engraftment and differentiation. Further modifications of the SCID model led to generation of NOD/SCID–IL2 receptor γ chain knock-out (NSG) strain, which supports robust normal human multilineage (myeloid and lymphoid) hematopoietic engraftment, as well as engraftment of acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) cells from patients.[92] The sensitivity of the transplant assay is further increased by direct intrafemoral injection into the BM cavity[93]; remarkably, in NSG recipients, human hematopoietic engraftment can be detected after intrafemoral transplantation of a single highly purified human HSC.[94] Just as the case in the study of murine microenvironment, the xenotransplantation model has an inherent limitation of requiring conditioning by sublethal irradiation to enable human hematopoietic engraftment.

Similar to mouse HSCs, human HSCs transplanted into mouse recipients also preferentially traffic to the trabecular bone and home next to the endosteal surface.[95] They are guided to their niches by the CXCL12–CXCR4 pathway and cell adhesion molecules such as very late antigen-4 (VLA-4), very late antigen-5 (VLA-5), and lymphocyte function-associated antigen-1 LFA-1; of note, CXCL12 is expressed by human OLCs, mesenchymal stromal, Nestin-positive, and endothelial cells. CD44 and hyaluronic acid cooperate with CXCL12 in human HSC homing.[96] Recent experiments identified $\alpha 6$ integrin CD49f as a novel marker for human HSCs, alluding to functional importance of HSC anchorage within BM microenvironment.[94]

The cellular components of the human HSC niche are yet to be identified. One potential candidate is a population of mesenchymal subendothelial cells expressing CD146, which can be prospectively isolated from human BM.[58] These perivascular cells were able to establish both bone and hematopoietic microenvironment upon subcutaneous transplantation; had a documented self-renewal capacity; and produced angiopoietin 1, a cytokine known to induce HSC quiescence. CD271 has been suggested as another marker for human hematopoiesis-supporting mesenchymal population[97]; in addition to CD146+ perivascular cells, it labels CD146-endosteal population, which co-localizes with hematopoietic CD34+ cells in human BM.

The limitations of our knowledge of human hematopoietic microenvironment led to current difficulties in achieving in vitro stem cell expansion using noncell autonomous means despite the potential benefits of doing so, especially in the context of cord blood transplantation when the number of donor cells is small. Although some of the cytokines involved in the maintenance of stem cell pool are known, very few factors that lead to a net increase in the HSC number have been discovered. One of them Sonic hedgehog protein, which has been shown to induce proliferation of primitive human hematopoietic cells when added to highly purified CD34+ CD38- lineage human cells[98]; this effect translated into increased level of progenitor expansion in NOD/SCID mice. The other two molecules are an engineered Notch ligand Delta 1[99] and prostaglandin E_2.[100] The latter molecule was identified in a high-throughput screen in zebrafish and found to enhance murine HSC localization in the BM after brief in vitro exposure to the compound. This resulted in a two- to

threefold increase in the number of HSCs compared with control (vehicle-exposed) cells. Current phase 1 studies are in progress to test the efficacy of these molecules for in vitro HSC expansion before cord blood transplantation.

HEMATOPOIEITIC MICROENVIRONMENT IN ACUTE LEUKEMIA AND MYELODYSPLASIA

Given a critical role of hematopoietic microenvironment in safeguarding cellular homeostasis in the BM, it is not surprising that alterations within it—either primary or induced by the presence of malignant cell population—have been proposed to be a contributing factor toward tumor initiation, maintenance, and resistance to treatment. Here, we will summarize recent experimental data, which reveal the role of specific cellular and molecular alterations within microenvironment in the pathogenesis of acute leukemia and myelodysplasia. For the review of this topic in other hematologic neoplasms, readers are referred to disease-specific chapters of this book.

Early in vitro studies alluded to significant contribution of nonhematopoietic BM cells (collectively termed *stroma*) to the pathogenesis of acute leukemia. For example, fibroblastic stromal cells from patients with AML were unable to support normal granulocytic-macrophage colony formation in contrast to those obtained from normal individuals. However, when the stromal cells were tested from patients in remission, they maintained growth of GM colonies similar to normal stroma.[101] Strikingly, when the patients relapsed, this GM colony-supporting ability was lost. In another series of observations, when nonadherent cells from continuous marrow cultures or GM-CSF–dependent progenitor cell lines were co-cultured with mouse stromal cells that had been previously irradiated, they developed factor-independence and multiple distinct karyotypic abnormalities[102]; upon subcutaneous injection, these newly transformed cell lines produced granulocytic monomyeloid tumors that spread to spleen, lymph nodes, and BM. Although by no means definitive, these studies suggested that either the altered stromal cells may contribute to the emergence of leukemia, or leukemia itself may affect the nonhematopoietic compartment. Both of these hypotheses found confirmation in the later studies reviewed below.

The idea of "niche-induced oncogenesis," or contribution of the microenvironment to the emergence of malignant disease, is supported by the clinical observation of donor-induced leukemia.[103] In this condition, which has a reported incidence between 0.12% and 5%, the leukemic clone arises from an apparently normal donor hematopoietic cells after allogeneic BM transplantation. Although the etiology is clearly multifactorial, damage to the BM microenvironment, either because of previous chemotherapy or pretransplant conditioning, may be an important contributing factor. In keeping with this idea, several experimental mouse models illustrate that microenviromental damage, either alone or in conjunction with corresponding molecular lesions in the hematopoietic compartment, can play a critical role in the initiation of malignant disease. The mice with deficiency of phosphatase and tensin homologue (PTEN) both in the microenvironment and HSC developed a myeloproliferative disorder, but PTEN deficiency in HSCs alone did not result in the disease.[104] Similarly, widespread deletion of retinoblastoma protein or retinoic acid receptor led to the development of myeloproliferative disorder, in the latter case purely because of gene deletion in the microenvironment deletion.[105,106] In the most recent study addressing this question, targeted deletion of the micro-RNA processing enzyme Dicer 1 in immature OLCs resulted in development of myelodysplasia and acute leukemia associated with independent complex genetic changes.[107] The effect of Dicer-1 deletion was entirely attributable to the microenvironment because transplantation of Dicer 1-deleted BM into normal microenvironment resulted in reversal of the myelodysplastic phenotype. Remarkably, hematopoietic abnormalities were observed when Dicer-1 was deleted in very immature OLCs (osterix+) but not in those at a more mature differentiation stage (osteocalcin+). Deletion of Scwachman-Diamond-Bodian syndrome gene in immature OLCs recapitulated the key features of the Dicer-1 deletion phenotype and implicated their role of OLCS in its pathogenesis. Taken together, the above data suggest that microenvironment is capable of contributing to dysplasia and possibly leukemogenesis by selecting for abnormal hematopoietic cells. Microenvironment-induced signals are therefore potential therapeutic targets in the setting of myelodysplasia.

In addition to the microenvironment contributing to disordered hematopoiesis, it may be affected by it. It has been shown that primary ALL and AML blasts are able to downregulate CXCL12 expression in the BM, causing the egress of normal CD34+ HSCs from the BM.[108] This process was mediated by the stem cell factor (CSF) secreted by leukemic blasts because neutralization of this cytokine with an antibody reversed the above changes. The "niche-modifying" ability of the leukemic cells in vivo is an area of ongoing investigation because it suggests that the leukemic niche can be molecularly distinct from the normal and therefore therapeutically targeted.

CXCR4 is expressed by LSCs, and the CXCR4–CXCL12 pathway is critical for homing and subsequent adhesion of LCSs to the BM microenvironment.[109,110] Of note, the level of CXCR4 is elevated in patients with AML and is associated with a poor outcome.[111] The presence of Flt3 internal tandem duplication (a poor prognostic factor in AML) is in turn associated with increased CXCR4 expression.[112] Experimentally, treatment of NOD/SCID mice transplanted with primary human AML cells using a neutralizing antibody against CXCR4 reduced the leukemic burden.[110] Follow-up studies confirmed the antileukemic effect of blocking CXCL12–CXCR4 axis using competitive antagonists of CXCR4 (AMD3100 and AMD3254) in mouse models of AML.[113,114] These findings formed the basis for ongoing clinical trials of CXCR4 antagonist AMD3100 (Plerixafor) as a chemosensitizing agent in AML.

Another example of LSC niche dependence is a cell adhesion molecule CD44, which is present on the surface of leukemic cells and interacts with hyaluronan on the endosteal surface. Blocking the interaction between CD44 and hyaluronan using activating CD4 antibody had significant effect on LSC eradication and even cured some mice.[115] The therapeutic effect of the antibody was more marked when it was administered soon after injection of human leukemic cells compared with the animals with established disease, suggesting that it acts predominantly at the stage when LCSs engage their respective niches. It is also possible that some of the effect of the CD44 antibody was attributable to differentiation induction in the LSCs. Nevertheless, this study provided a proof-of-principle demonstration that LSCs interaction with the niche is required for their survival and leukemia progression and thereby raised the potential for targeting therapy.

Other molecular mediators of LSC–microenvironment interaction have also been identified. B4 integrin (also known as very late antigen 4) mediates lodgment of leukemic cells in the BM and interacts with fibronectin to confer resistance to cytosine arabinoside-induced apoptosis.[116] Integrin ligation triggers prosurvival pathways, and the blocking antibody leads to reduction in the level of leukemic burden and a modest prolongation of the lifespan in human AML-transplanted animals. Similar protective role for AML blasts has been observed for β1 and β2 integrins. IL-3 receptor α chain (CD123) also contributes to LSC survival, at least partly through being involved in controlling LSC homing to the BM[117]; CD123 blocking antibody demonstrated considerable antileukemic activity, which was also attributable to promoting immune-mediating destruction of leukemic cells—the idea that has been explored further in the studies of blocking a macrophage-associated molecule CD47 (see below).

Little is known about the cells that make up the leukemic niche and the mechanisms by which they control LSC behavior. Most experiments addressing this question are based on co-localization of transplanted leukemic cells with one of the "niche" cells, which are either fluorescently labeled or morphologically defined. However, to date, no cell ablation experiments have been performed to show a nonredundant role of a particular cell type within a leukemic niche, and given a microanatomic proximity between "niche" cells as discussed above, it is likely that several of them participate in formation

of leukemic microenvironment. Currently, there is circumstantial evidence for the role of endothelial cells, OLCs, and macrophages in the leukemic microenvironment.

Endothelial Cells

Increased vascularization is seen in AML, ALL and preleukemic conditions such as myelodysplastic syndrome and myeloproliferative neoplasms. Leukemic blasts and BM microenvironment secrete several angiogenic growth factors such as VEGF, basic FGF, and angiopoietins.[118] Abnormal expression of matrix metalloproteinases, which are involved in regulation of angiogenesis, has also been documented. In vivo imaging studies examining early homing pattern of Nalm-6 ALL cells point to specific vascular subdomains within CD31-positive endothelium, which express CXCR4 and E-selectin and favor the lodgment of leukemic cells.[53] Importantly, these subdomains are shared by normal hematopoietic progenitors, suggesting that leukemic cells outcompete their normal counterparts for the vascular niches during disease progression. Several phase II studies are currently underway to assess the clinical efficacy of inhibition of VGEF–VEGF receptor axis in refractory and resistant AML.[119] It is becoming clear that antiangiogenic agents in leukemia are insufficient as monotherapy, but larger studies and longer follow-up are needed to assess their benefit as a part of multiagent chemotherapy.

Osteolineage Cells

Osteolineage cells are thought to participate in formation of protective leukemic niche and confer cell cycle quiescence and chemoresistance.[120] This would be consistent with the role of OLCs in normal HSC niche, such as induction of quiescence and negative regulation of HSC self-renewal (see earlier discussion). Transplanted human AML LSCs home next to the endosteal surface, and the majority of them remain in the G0 phase of the cell cycle.[121] The endosteal surface serves as the main site of residual disease after administration of cytosine arabinoside. The proportion of cycling LSCs increases after GCSF-induced mobilization, and this has a chemosensitizing effect on the LSCs, resulting in prolongation of survival in AML-engrafted animals treated with a combination of GCSF and cytosine arabinoside compared with cytosine arabinoside alone. However, it is unclear whether this effect is because of a specific LSC-OLC interaction or simply the result of LSC "moving away" from the niche after G-CSF treatment. Further studies are therefore required to more definitively address the role of OLC in microenvironment-influenced sensitivity to chemotherapy.

Macrophages

Bone marrow macrophages are emerging as another key functional component of the leukemic niche because the interaction of signal regulatory protein α (SIRPα) on the macrophages and CD47 on LSCs appears to protect the LSCs from phagocytosis.[122,123] CD47 is more highly expressed on LSCs, is associated with Flt3-ITD mutation, and independently predicts worse prognosis. Mechanistically, CD47 acts as a "do not eat me" signal for the macrophages. Blocking CD47 antibody produces depletion of AML in xenotransplantation models and specific eradication of LSCs. Strikingly, CD47 antibody also demonstrated potent antitumor effect in xenotransplantation models of ALL and non-Hodgkin lymphoma.[124,125]

Hypoxia

Emerging experimental evidence (using the chemical marker of hypoxia pimidazole) suggests that leukemic BM niches are hypoxic and that leukemic cells adapt to hypoxic conditions.[126] Although low oxygen tension within the leukemic niche remains to be directly demonstrated, the findings of overexpression of the key hypoxia-response factor HIF1α in clusters of ALL cells, together with increased angiogenesis and production of VEGF by the ALL blasts support this hypothesis.[127] In several xenograft models, hypoxia-activated dinitrobenzamide mustard, PR-104, prolonged survival of NSG mice engrafted with ALL cell line Nalm-6.[126] Although very preliminary, these important results identify hypoxia as another potential avenue of niche-based antileukemic therapy.

FUTURE DIRECTIONS

Although the concept of specific microenvironment for different hematopoietic compartments was first proposed more than 100 years ago, it was not until recently that the existence of the "niches" has been experimentally proven and the molecular factors involved in cellular interactions have been discovered.

Our current knowledge of the hematopoietic microenvironment has been evolving in parallel and often leading that in other stem cell systems. It appears that fundamental components and molecular pathways are highly conserved among evolutionary diverse species, although their role in specific niches may vary. These include supporting stromal cells secreting soluble molecules regulating stem cell self-renewal (bone morphogenic protein and Wnt signaling), extracellular matrix proteins that serve as stem cell anchors (integrins), blood vessels that are responsible for nutritional support and transit of stem cells in and away from the niche, and neural inputs for integrating signals from different systems. It is therefore likely that future studies in spatial and molecular organization of other stem cell niches will inform the knowledge of hematopoietic niches and vice versa.

With a rapidly increasing number of cell types known to be involved in hematopoietic niches (and the number of different cytokines they produce, which will inevitably follow), it will be important to use a "network" approach—similar to the one used for analysis of transcriptional networks—to understand how these multiple factors act in concert to control location, proliferation, and trafficking of HSCs and more mature cells in the BM. It is possible that these factors work in combinatorial manner, ultimately creating a "niche code" that is designed to suit a specific physiologic situation.[128]

A particularly notable development over the recent years has been our improvement in understanding of the role of microenvironment in initiation and maintenance of malignant disease, although many questions remain. We still know very little about the molecular mediators of "niche-induced oncogenesis" and those involved in microenvironment-induced chemoresistance. Recent advances in xenotransplantation assay using highly immunocompromised mouse strains for the study of normal and leukemic hematopoiesis, together with further molecular insights into biology of leukemic stem cells, will provide an opportunity to address these issues.

Therapeutic manipulation of the hematopoietic microenvironment remains an ultimate goal of ongoing research. Clearly, the effort of the next several years will be focused on translating the wealth of data obtained from the animal models into human biology and the clinic. This work has already started with the clinical trials of ex vivo HSC expansion before cord blood transplantation. A number of clinical trials are also underway to examine the efficacy of niche-directed therapies in hematologic malignancies. Although the animal data suggest that targeting the niche alone is often insufficient to achieve cure, especially in established disease, this approach has been successful in regaining leukemia chemosensitivity to commonly used agents and may become a valuable component of future treatment protocols. Gaining a deeper insight into the molecular distinctions between normal and malignant niches will enable better understanding of "niche competition" between normal and leukemic populations and lead to development of novel approaches based on eradication of leukemic cells and fostering normal hematopoiesis through manipulation of niche-derived signals.

CHAPTER 10

CELL ADHESION

Rodger P. McEver and Francis W. Luscinskas

Cell adhesion is essential for the development and maintenance of multicellular organisms. Cell-to-cell and cell-to-matrix adhesion provide a mechanism for intercellular communication and to define the architecture of organs. The regulated nature of cell adhesion is particularly evident in the hematopoietic system, where blood cells routinely make transitions between nonadherent and adherent phenotypes during differentiation and in response to stimuli in the circulation or extravascular tissues.

In the bone marrow (BM), hematopoietic stem cells reside in a specialized microenvironment called the *stem cell niche,* and their proliferation and differentiation are controlled not only by soluble growth factors but also by adhesion to stromal cells and matrix molecules. Weakening of these adhesive interactions is required for mature blood cells to enter the circulation. Circulating erythrocytes normally remain nonadhesive until they are finally cleared by the reticuloendothelial system. Other circulating blood cells often participate in regulated adhesive events during their lifespan. For example, prothymocytes adhere to components of the thymus, where they undergo further maturation before reentering the circulation. T cells regularly stick to the specialized high endothelial venules of lymphoid tissues, migrate into these tissues for sampling of processed antigens, and then exit via the lymphatics. During inflammation, specific classes of leukocytes roll at very low velocity on the endothelium that line all blood vessels, then adhere more tightly, and finally emigrate between endothelial cells into the tissues. There, neutrophils and monocytes phagocytose invading pathogens, and lymphocytes adhere to antigen-presenting cells such as dendritic cells, B cells, and macrophages. During hemorrhage, platelets stick to exposed subendothelial matrix components, spread, and recruit additional platelets into large aggregates that serve as an efficient surface for thrombin and fibrin generation. Leukocytes also adhere to activated platelets and to other leukocytes, and platelets roll on the endothelium. When activated, endothelial cells increase expression of molecules that affect the adhesiveness of platelets or leukocytes. Tight contacts between adjacent endothelial cells also regulate access of blood cells to the underlying tissues.

ADHESION MOLECULES

Cells adhere through noncovalent bond formation between macromolecules on cell surfaces with macromolecules on other cell surfaces or in extracellular matrix (ECM). These interactions involve either protein–protein or protein–carbohydrate recognition. Although some adhesion molecules are expressed only by blood or endothelial cells, most also are synthesized by other cells. Many adhesion molecules can be grouped into families according to related structural and functional features.

EXTRACELLULAR MATRIX PROTEINS

The ECM provides structural and mechanical support for many tissues and spatial cues that enable cell–cell communication and signaling. The principal constituents of the ECM are adhesive proteins and proteoglycans. The major proteins are collagens, von Willebrand factor (vWF), thrombospondin, elastin, fibronectin, laminin, and vitronectin. These proteins are large and often highly extended and consist of multiple domains with different binding functions. In some proteins such as fibronectin, alternative splicing can increase diversity by producing molecules with variable numbers of domains. In addition, stretching of fibronectin can expose cryptic binding sites. The many binding domains allow adhesive proteins to interact with each other as well as with cell-surface receptors, resulting in multipoint contacts that stabilize matrix structure. One adhesive protein, fibrinogen, is found predominantly in plasma but also may be deposited in exposed subendothelial matrix after vascular injury. Fibronectin, vitronectin, thrombospondin, and vWF are located predominantly in the ECM but also are found in plasma. Several adhesive proteins also are stored in α-granules of platelets, where they are secreted after platelet activation at sites of vascular injury. Similarly, the endothelium stores adhesive proteins in storage granules, called *Weibel-Palade bodies,* that are released upon injury or activation.

Proteoglycans contain protein cores to which are covalently attached many glycosaminoglycans-long linear polymers of repeating disaccharides. Most proteoglycans are in the ECM, but some are anchored on cell surfaces through a core protein that contains a membrane-spanning domain. Hyaluronan is a unique glycosaminoglycan that forms polymers with molecular masses up to several million daltons that are not covalently attached to a protein. Hyaluronan forms noncovalent interactions with globular domains on the protein core of proteoglycans and with a small molecule called *link protein*. The resultant hyaluronan–proteoglycan complexes can become very large, contributing to the structural stability of matrix and function as space fillers during embryonic development. Hyaluronan can also bind to cell-surface receptors and is also abundantly produced during wound healing.

INTEGRINS

Integrins are a broadly distributed group of cell-surface adhesion receptors that consist of noncovalently associated α- and β-subunits (Fig. 10-1 and Table 10-1). There are 18 α chains and eight β chains that pair in many, but not all, of the possible combinations. All blood cells have several different integrins. The four β2 integrins, each paired with a unique α subunit, are expressed only by leukocytes, and the αIIbβ3 integrin (glycoprotein IIb–IIIa [GPIIb–IIIa]) is expressed only by megakaryocytes and platelets. Multidomain adhesive proteins of the ECM are ligands for many integrins. Integrins are unusual adhesion molecules because they usually reside in an inactive state on the cell surface until they receive an activating signal. Some integrins bind to specific domains of several different proteins, and some adhesive proteins bind to several different integrins. These interactions generally mediate cell–matrix adhesion. A unique feature of integrins is transmission of signals in both directions across the cell plasma membrane. Integrin binding to matrix informs the interior of the cell (outside-in) and intracellular signals or conditions inside cells transmit signals outward (inside-out) that regulate binding to matrix or to adhesion receptors on the surface of adjacent cells. Force can also regulate integrin adhesive function. The application of tension to integrins can increase ligand binding, and a reduction in

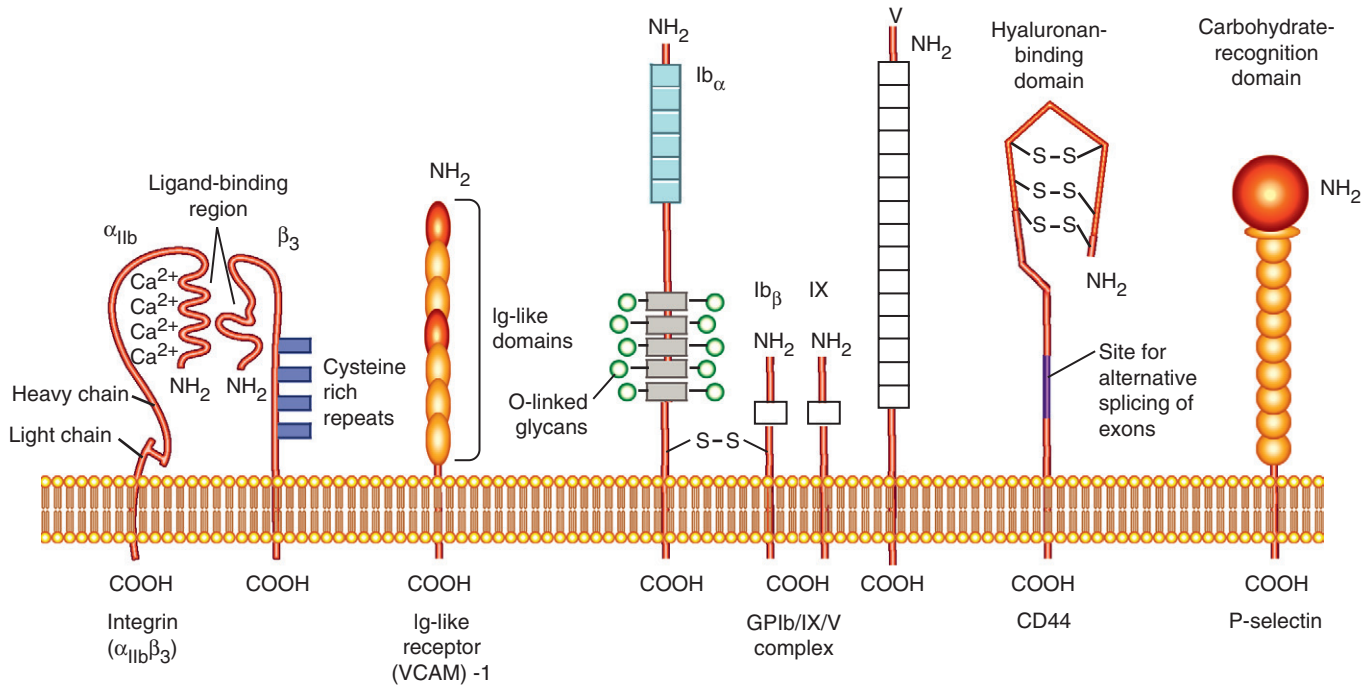

Figure 10-1 SCHEMATIC DIAGRAMS OF SEVERAL TYPES OF CELL-SURFACE ADHESION RECEPTORS. Integrins consist of noncovalently linked α and β subunits, both of which contribute to ligand binding. The platelet αIIbβ3 integrin is illustrated at *far left*. Immunoglobulin (Ig)-like receptors contain a variable number of Ig homology domains, of which some bind ligands and others extend the ligand-binding domains from the membrane. Shown *second from left* is vascular cell adhesion molecule-1 (VCAM-1), which contains seven Ig domains; the two domains that bind to integrins are *shaded*. The platelet glycoprotein Ib–IX–V (GPIb–IX–V) complex, depicted in the *middle diagram*, consists of several leucine-rich protein subunits. CD44, illustrated next, contains an amino-terminal (*N*-terminal) domain that binds to hyaluronan. Each of the selectins contains an *N*-terminal carbohydrate recognition domain that binds sialylated and fucosylated oligosaccharides on specific cell-surface GP ligands. Illustrated at *far right* is P-selectin, the largest of the three selectins.

tension lessens integrin adhesiveness. Cell–cell interactions result from integrin recognition of cell-surface members of the immunoglobulin superfamily. Binding of fibrinogen to αIIbβ3 integrins on adjacent platelets creates a molecular bridge that promotes platelet aggregation. Furthermore, fibrinogen simultaneously binds to the αMβ2 integrin on leukocytes and to an immunoglobulin-like receptor on endothelial cells, promoting leukocyte adhesion to the endothelium.

IMMUNOGLOBULIN-LIKE RECEPTORS

Immunoglobulin superfamily members contain a variable number of disulfide-stabilized motifs similar to those in antibodies, which are linked to transmembrane and cytoplasmic domains (Table 10-2; see also Fig. 10-1). The immunoglobulin-like motif provides a framework on which specific recognition structures for other proteins can be added. Some of these motifs also recognize glycoconjugates. The immunoglobulin-like molecules, intercellular adhesion molecule 1 and 2 (ICAM-1 and ICAM-2), and vascular cell adhesion molecule 1 (VCAM-1), expressed on endothelial cells, as well as ICAM-3, expressed on leukocytes, mediate cell–cell contact through recognition of specific integrins on leukocytes. ICAM-4, expressed on erythroid precursors, binds to integrins on stromal cells of BM, which may regulate erythropoiesis. ICAM-5 is restricted to neural tissues. The immunoglobulin-like GPVI on platelets promotes cell activation by binding to collagen exposed on damaged blood vessels. Interactions between immunoglobulin-like molecules help to mediate adhesion between T cells and antigen-presenting cells. Thus, whereas the immunoglobulin-like molecules CD8 and CD4 on T cells bind to the conserved membrane-proximal domains of class I and class II major histocompatibility complex (MHC) proteins, respectively, the T-cell receptor (CD3) binds to the polymorphic antigen-presenting domain. In addition, the immunoglobulin-like proteins CD2 and CD28 on T cells bind to the immunoglobulin-like protein leukocyte function-associated antigen-3 (LFA-3) and B7-1, respectively, on antigen-presenting cells. The immunoglobulin-like receptor platelet and endothelial cell adhesion molecule-1 (PECAM-1) (CD31) uses homotypical interactions to promote contacts between adjacent endothelial cells and to mediate adhesion of leukocytes to platelets and endothelium. The immunoglobulin-like junctional adhesion molecules (JAMs), expressed on endothelial and epithelial cells and leukocytes, regulate endothelial and epithelial cell junctions, paracellular permeability, and leukocyte trafficking between endothelial and epithelial cells by homotypical interactions or by heterotypical interactions with integrins. JAM-A, the founding member of this family, functions as a homodimer and transmits intracellular signals critical for its function in regulation of endothelial and epithelial permeability.

OTHER ADHESION RECEPTORS THAT MEDIATE PROTEIN–PROTEIN INTERACTIONS

Cadherins are cytoskeletally linked membrane proteins that mediate cell–cell contact in many organs through homotypical binding to cadherins on adjacent cells (Table 10-3). Cadherins have not been described on blood cells but are found on endothelial cells, where, similar to PECAM-1 and JAMs, they help form cell junctions and participate in the process of leukocyte migration across endothelial cell-to-cell borders, termed *diapedesis* or *transendothelial migration*.

The GPIb–IX–V complex on platelets consists of leucine-rich protein subunits (see Fig. 10-1). Under conditions of high shear stress such as those found in arterial circulation, this complex promotes the initial platelet adhesion to injured vessels by binding to vWF exposed in the subendothelium. It also may assist interactions with other

Table 10-1 Integrins on Blood Cells

Integrin Designation	Other Name(s)	Expressed by	Ligand(s)	Function(s)
$\alpha_1\beta_1$	VLA-1	Leukocytes, other cells	Collagens, LM	Adhesion to ECM
$\alpha_2\beta_1$	VLA-2 GPIa/IIa	Leukocytes, platelets, other cells	Collagens, LM	Adhesion to ECM
$\alpha_3\beta_1$	VLA-3	Leukocytes, other cells	Collagens, LM, FN	Adhesion to ECM
$\alpha_4\beta_1$	VLA-4	Monocytes, lymphocytes, eosinophils	VCAM-1, FN	Adhesion to cells, ECM
$\alpha_5\beta_1$	VLA-5 GPIc/IIa	Leukocytes, platelets, other cells	FN	Adhesion to ECM
$\alpha_6\beta_1$	VLA-6 GPIc/IIa	Leukocytes, platelets, other cells	LM	Adhesion to ECM
$\alpha_9\beta_1$		Neutrophils	VCAM-1	Adhesion to ECs
$\alpha_L\beta_2$	LFA-1 CD11a/CD18	Leukocytes	ICAM-1, -2, -3	Leukocyte aggregation and adhesion
$\alpha_M\beta_2$	MAC-1 CR3 CD11b/CD18	Neutrophils, monocytes	ICAM-1, FIB, CR for iC3b	Neutrophil aggregation and adhesion to ECs
$\alpha_X\beta_2$	P150,95 CD11c/CD18	Neutrophils, monocytes	CR for iC3b	Adhesion to ECs
$\alpha_D\beta_2$	CD11d/CD18	Eosinophils, monocytes, lymphocytes	VCAM-1, ICAM-3	Adhesion to leukocytes and to ECs
$\alpha_{IIb}\beta_3$	GPIIb/IIIa	Platelets	FIB, FN, vWF, VN, TSP	Platelet adhesion and aggregation
$\alpha_v\beta_3$	VN receptor	Platelets, ECs	FIB, FN, vWF, VN, TSP, collagens	Platelet adhesion, angiogenesis
$\alpha_4\beta_7$	LPAM-1	Lymphocytes	VCAM-1, MAdCAM-1, FN	Lymphocyte adhesion to ECs and ECM

CR, Complement receptor; *EC*, endothelial cell; *ECM*, extracellular matrix; *FIB*, fibrinogen; *FN*, fibronectin; *GP*, glycoprotein; *LFA-1*, leukocyte function-associates antigen; *LM*, laminin; *LPAM-1*, lymphocyte Peyer patch adhesion molecule; *MAdCAM-1*, mucosal addressin cell adhesion molecule-1; *TSP*, thrombospondin; *VCAM-1*, vascular cell adhesion molecule-1; *VLA*, very late-appearing antigen; *VN*, vitronectin; *vWF*, von Willebrand factor.

Table 10-2 Immunoglobulin-Like Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
ICAM-1		Macrophages, EC, other cells	$\alpha_M\beta_2$, $\alpha_L\beta_2$, FIB	T-cell responses, leukocyte adhesion to EC
ICAM-2		EC	$\alpha_L\beta_2$	Leukocyte adhesion to EC
ICAM-3		Leukocytes	$\alpha_L\beta_2$	T-cell responses, leukocyte aggregation
ICAM-4		Erythroid precursors	$\alpha_4\beta_1$, $\alpha_v\beta_3$, $\alpha_{IIb}\beta_3$	Regulate erythropoiesis
GPVI		Platelets	Collagen	Platelet adhesion and activation
PECAM-1	CD31	Leukocytes, platelets, EC	PECAM-1	EC junctions, leukocyte transmigration, cell signaling
VCAM-1		Activated EC, smooth muscle cells	$\alpha_4\beta_1$, $\alpha_4\beta_7$	Mononuclear cell adhesion to EC
MAdCAM-1		EC of Peyer patches	$\alpha_4\beta_7$	Lymphocytes homing
Siglecs		Leukocyte subsets	Sialylated glycans	Regulate B-cell activation, innate immunity?, hematopoiesis?
JAMs		EC	JAMs, $\alpha_L\beta_2$, $\alpha_4\beta_1$	EC junctions, leukocyte transmigration
CD2		T cells	LFA-3*	T-cell responses
CD4		T cells	Class II MHC*	T-cell responses
CD8		T cells	Class I MHC*	T-cell responses
CD3	T-cell receptor	T cells	Antigen on MHC*	T-cell responses
CD28	Costimulatory molecule	T cells	B7-1 (CD80)	T-cell responses

ICAM-1, -2, -3, -4, Intercellular adhesion molecules; *JAM*, junctional adhesion molecule; *MHC*, major histocompatibility complex; *PECAM-1*, platelet and endothelial cell adhesion molecules-1. For other abbreviations, see Table 10-1 footnotes.
*LFA-3 and classes I and II MHC molecules are also immunoglobulin-like receptors.

Table 10-3 Other Adhesion Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
Cadherins		EC, many other cells	Homotypic binding	Formation of EC junctions
GPIb/IX/V		Platelets	vWF	Platelet adhesion to ECM under shear
CD36	GPIV	Platelets, many other cells	Collagens, TSP	Platelet adhesion to ECM
CD44		Leukocytes, other cells	Hyaluronan, serglycin	Lymphopoiesis, lymphocyte activation
DC-SIGN		Dendritic cells	Mannosylated glycans, other glycans	Regulate T-cell–dendritic cell interactions, recognize pathogens
NK cell receptors		NK cells	MHC molecules	Recognition of virus-infected or other foreign cells

DC-SIGN, Dendritic cell-specific ICAM-3 grabbing nonintegrin; *MHC,* major histocompatibility complex; *NK,* natural killer. For other abbreviations, see Table 10-1 footnotes.

Table 10-4 Selectins

Name	Other Name	Expressed by	Ligand	Ligands Expressed by	Function(s)
P-selectin	CD62P GMP-140 PADGEM	Thrombin-activated platelets and EC, cytokine-activated EC	PSGL-1, GPIbα	Leukocytes, platelets	Leukocyte adhesion to activated EC and platelets
E-selectin	CD62E ELAM-1	Cytokine-activated EC	PSGL-1, other sialylated and fucosylated GPs	Leukocytes	Leukocyte adhesion to activated EC
L-selectin	CD62L LECAM-1 LAM-1	Leukocytes	PSGL-1, also GlyCAM-1, CD34, and other mucins on EC of lymph nodes	Leukocytes, EC or lymph nodes	Leukocyte adhesion to other leukocytes; lymphocyte homing to lymph nodes

EC, Endothelial cell; *ELAM-1,* endothelial leukocyte adhesion molecule-1; *Gly-CAM-1,* glycosylation-dependent cell adhesion molecule-1; *GMP-140,* granule membrane protein-140; *LAM-1,* leukocyte adhesion molecule-1; *LECAM-1,* leukocyte endothelial cell adhesion molecule-1; *PADGEM,* platelet activation-dependent granule external membrane protein; *PSGL-1,* P-selectin glycoprotein ligand-1.
The selectins bind to sialylated, fucosylated, and (in some cases) sulfated oligosaccharides on specific glycoproteins, of which only some have been identified.

platelets or with endothelial cells by binding to P-selectin, which normally binds to glycoconjugates, and it may assist platelet adhesion to leukocytes by binding to the integrin $\alpha_m\beta_2$.

CD36 is a receptor with at least two membrane-spanning domains that is expressed on many cell types. On platelets, it has been implicated as a receptor for collagen and perhaps for thrombospondin; both interactions could facilitate adhesion to the subendothelial matrix at sites of hemorrhage.

LECTIN ADHESION RECEPTORS

CD44 is an unusual transmembrane GP expressed to variable degrees on many subsets of leukocytes (see Fig. 10–1). It has a membrane-distal domain that is structurally related to link protein of ECM, and similar to link protein, can bind to hyaluronan. CD44 also binds to the serglycin, a proteoglycan secreted by hematopoietic cells. The hyaluronan-binding function of CD44 may modulate a number of leukocyte responses. The most clearly demonstrated function is in lymphopoiesis, where maturation of lymphocyte precursors requires contacts with BM stromal cells bearing surface hyaluronan. CD44–hyaluronate interactions also may promote lymphocyte entry to and transit through organized lymphoid tissues. The membrane-proximal regions of CD44 are structurally diverse because of the insertion of variable numbers of domains through alternative splicing. These insertions may regulate the ability of CD44 to bind hyaluronan and may mediate postbinding events that affect cell signaling.

The selectins are a group of three receptors that terminate in a membrane-distal carbohydrate-recognition domain related to those in Ca^{2+}-dependent (C-type) animal lectins such as the hepatic asialoglycoprotein receptor (see Fig. 10-1). L-selectin is expressed on leukocytes, E-selectin on cytokine-activated endothelium, and P-selectin on macrophages, platelets, and endothelial cells exposed to secretagogues such as thrombin or histamine (Table 10-4). The selectins mediate leukocyte adhesion to platelets, endothelium, or other leukocytes through Ca^{2+}-dependent interactions of the carbohydrate-recognition domains with cell-surface carbohydrates on apposing cells. High-affinity binding appears to require specific carbohydrate structures displayed on a limited number of membrane GPs. The best-characterized GP ligands for selectins are mucins that have large numbers of clustered, sialylated *O*-linked oligosaccharides. Site-specific construction of *O*-glycans with specific sialylated, fucosylated, and (in some cases) sulfated moieties is required for these mucins to bind optimally to selectins. In the case of one mucin, P-selectin GP ligand-1 (PSGL-1), sulfation of tyrosine residues near a specific *O*-glycan is required for binding to P- and L-selectin.

Dendritic cells and related macrophages express a novel group of C-type lectins, of which the best-characterized is dendritic cell-specific ICAM-3–grabbing nonintegrin (DC-SIGN). DC-SIGN binds to particular oligosaccharides on ICAMs, thereby regulating T-cell and dendritic cell function during antigen presentation. It also binds to glycans on a variety of pathogens, which may have critical roles in innate immunity. Natural killer cells express a different group of proteins with some containing membrane-distal C-type lectin-like domains. Although these receptors are important for interactions of natural killer cells with target cells, they may bind to proteins rather than to glycoconjugates.

Siglecs are a subgroup of membrane proteins of the immunoglobulin superfamily that bind to carbohydrates instead of to proteins (see Table 10-2). The first two amino-terminal (*N*-terminal) domains appear to be necessary and sufficient for carbohydrate recognition. The *N*-terminal domain is a V-type structure that includes an unusual disulfide bond that is not found in the more common C-type immunoglobulin domains. Siglecs bind well to sialylated glycans on some

but not all GPs. Different siglecs preferentially recognize sialic acid that is linked α2,6-, α2,8-, or α2,3- to an underlying galactose residue. Most siglecs have immune receptor tyrosine-based inhibitory motifs and transmit inhibitory signals. Siglecs can form *cis* interactions with other GPs on the same cell or *trans* interactions with GPs on another cell. The best-characterized example is CD22, which negatively regulates B-cell activation when it engages sialylated GPs. Sialoadhesin, expressed on BM macrophages, may regulate hematopoietic cell differentiation.

LIGAND BINDING VERSUS CELL ADHESION

As with all noncovalent macromolecular interactions, adhesion molecules bind to each other with equilibrium affinities that are defined by their association and dissociation rates. However, the efficiency of cell adhesion is not simply a function of the solution-phase equilibrium affinities of adhesion molecules for one another. Adhesion molecules in cell membranes and matrix are limited primarily to two dimensions, and even low-affinity molecular interactions may stabilize adhesion if there is time for sufficient bonds to form along the plane of cell contact. The efficiency of cell attachment and the ensuing strength of adhesion reflect multiple factors that dictate the probability of formation of bonds between adhesion molecules on cell or matrix surfaces. The kinetics of bond formation and dissociation are especially important for certain kinds of cell adhesion. Furthermore, interactions between cell adhesion molecules are subjected to force, which affects the lifetimes of adhesive bonds. This is particularly true in the circulation, where platelets and leukocytes must rapidly adhere to the blood vessel wall and withstand forces applied by the wall shear stresses of flowing blood. Other factors that affect bond formation include the number of adhesion molecules on a cell or matrix surface, the distance the binding domain of an adhesion receptor protrudes from the cell membrane, the lateral mobility of receptors, receptor dimerization, and the clustering of receptors on microvilli or other membrane domains. Cell adhesion can be further stabilized by events that occur after the initial interactions of adhesion molecules. For example, the cytoplasmic domains of many adhesion molecules bind to cytoskeletal components, allowing clustering of receptors into surface patches that strengthen adhesion, thereby promoting cell spreading or migration.

REGULATION OF ADHESION RECEPTORS

To prevent inappropriate interactions of cells with each other or with ECM, the expression and function of adhesion receptors must be tightly controlled. Three primary control mechanisms are used: (1) the rate of synthesis of the receptor, (2) the time during which the receptor is displayed on the cell surface, and (3) the binding affinity or avidity of the receptor for ligands (Table 10-5). All of these mechanisms are used to control interactions of blood and vascular cells.

Table 10-5 Regulation of Adhesion Receptors

Mechanism	Example
Synthesis	Erythroid precursor synthesis of $\alpha_5\beta_1$ Lymphocyte synthesis of CD44 Cytokine-induced synthesis of E-selectin, P-selectin, ICAM-1, and VCAM-1 by endothelial cells
Surface expression	Proteolytic cleavage of L-selectin from leukocytes Redistribution of P-selectin from granule membranes to plasma membrane of platelets and endothelial cells Endocytosis of P- and E-selectin on endothelial cells
Ligand affinity	Activation-induced increased affinity of many integrins for their ligands Activation-induced increased affinity of CD44 for hyaluronan

For abbreviations, see Table 10-1 footnotes.

REGULATION OF SYNTHESIS

The synthesis of many adhesion receptors is regulated. Erythroid precursors synthesize integrins that mediate their interactions with stromal cells and with ECM in the BM. As the precursors mature, synthesis ceases, resulting in loss of expression of cell-surface integrins by the time a mature erythrocyte enters the circulation. Lymphocyte precursors synthesize CD44 during differentiation in the BM, stop synthesis before release, and resume synthesis during maturation in the thymus. On exposure to antigens, immunologically naive lymphocytes synthesize increased amounts of several adhesion receptors and chemokine receptors during their conversion to the effector phenotypes; this process presumably allows these cells to become more adhesive in response to a subsequent antigenic challenge. Endothelial cells in postcapillary venules of the peripheral vasculature express very low, if any, levels of adhesion molecules that bind leukocytes. When exposed to inflammatory cytokines such as tumor necrosis factor-α and interleukin-1 (IL-1) or bacterial endotoxin, endothelial cells transiently increase synthesis of E- and P-selectin, ICAM-1, and VCAM-1, resulting in an adhesive surface for leukocytes.

REGULATION OF SURFACE EXPRESSION

The surface expression of some adhesion receptors is tightly controlled. L-selectin is present on the plasma membrane of leukocytes, where it is available to bind to ligands on the endothelial cell surface. Stimulation of the leukocyte causes L-selectin to be shed into the plasma by proteolytic cleavage. P-selectin is constitutively synthesized by megakaryocytes (where it is incorporated into platelets) and by endothelial cells. Rather than being directly delivered to the plasma membrane, it is sorted into secretory storage granules: the α granules of platelets and the Weibel–Palade bodies of endothelial cells. On stimulation of these cells by agonists such as thrombin, P-selectin is rapidly transported to the cell surface during fusion of granule membranes with the plasma membrane. When they are on the surface of the endothelium, both E-selectin and P-selectin are internalized and delivered to lysosomes for degradation. The cytoplasmic domain of P-selectin contains signals that direct sorting into secretory granules, internalization through coated pits of the plasma membrane, and movement from endosomes to lysosomes; the latter two signals probably also are present in the cytoplasmic domain of E-selectin. The net result of these events is to control the duration of exposure of E- and P-selectin on the endothelium, where they can mediate adhesion of leukocytes. Activation of leukocytes also mobilizes a pool of β_2 integrins from storage compartments to the plasma membrane, although some of these molecules also are constitutively expressed on the cell surface. Finally, platelet activation redistributes a portion of the GPIb–IX–V complexes from ligand-accessible positions on the plasma membrane to sequestered, invaginated membrane domains known as the *surface-connected canalicular system*. This process, which requires interactions of the cytoplasmic domain of GPIb–IX–V with the cytoskeleton, may serve to downregulate GPIb-mediated adhesion of platelets to immobilized vWF.

REGULATION OF BINDING AFFINITY

Regulation of binding affinity is an important control mechanism for other adhesion receptors. Many integrins are constitutively present on the cell surface but interact poorly with their ligands. Cell activation by a number of agonists induces conformational changes in

integrins so that they effectively recognize their ligands. An example is the $\alpha_{IIb}\beta_3$ integrin, which requires platelet stimulation to bind fibrinogen; if this binding affinity were not regulated, circulating platelets would indiscriminately aggregate in the fibrinogen-rich plasma milieu. The cytoplasmic domains of integrins can exert both positive and negative influences on binding affinity. Binding of specific cytoplasmic proteins to these domains may propagate structural changes to the extracellular ligand-binding regions of the integrins. Three-dimensional structures of integrins suggest that the integrin "headpiece" that contains the ligand-binding site faces down toward the membrane in the inactive conformation and rapidly extends upward in a "switchblade"-like opening motion on activation. Low-affinity ligand binding may stabilize some active conformations of integrins, perhaps explaining why integrins on unactivated cells will sometimes bind to immobilized, multivalent adhesive proteins but not to the same proteins in solution. Cellular activation also may regulate the binding avidities of CD44, L-selectin, P-selectin, and some integrins through changes in membrane distribution engineered by interactions of their cytoplasmic domains with the cytoskeleton or with clathrin-coated pits.

CELL SIGNALING THROUGH ADHESION MOLECULES

In addition to their roles in cell–cell and cell–matrix contacts, adhesion molecules may cause cell signaling through indirect or direct mechanisms. Proteoglycans in the ECM can sequester growth factors that can be released to bind to surface receptors on nearby cells. Some chemoattractants bind to proteoglycans on the surface of endothelial cells, where they can activate adherent leukocytes. Binding of adhesive ligands to cell-surface integrins, GPIb–IX–V, CD44, cadherins, CD36, PECAM-1, selectins, and perhaps other receptors can directly trigger intracellular events. The consequences of such signaling include changes in affinity or avidity of other adhesion receptors for their ligands, shape change, secretion, proliferation, synthesis of cytokines and other molecules, and migration. In some cases, binding of a monovalent adhesive ligand to a receptor may induce a signal. More commonly, signaling requires cross-linking of several receptors through interactions with multivalent ligands in matrix or on apposing cells.

Many studies of adhesion receptor signaling have focused on integrins. Binding of the same ligand to different integrins can mediate different responses in the same cell. Furthermore, ligand binding to the same integrin expressed in different cells can result in different signals. These data suggest that very specific interactions occur between ligand-occupied integrins and intracellular components. The cytoplasmic domains of integrins are essential for initiating signaling. Tyrosine kinases have been localized at the interaction zones between integrins, the cytoskeleton and several adaptor and effector molecules, and tyrosine phosphorylation of a number of proteins accompanies integrin-mediated cell signaling. Tyrosine phosphorylation initiates a cascade of signaling events, including the activation of serine/threonine kinases, which cause a variety of cellular responses. Ligand binding to integrins also results in generation of lipid second messengers, alkalization of the cytoplasm, and influxes of Ca^{2+}.

COOPERATIVE INTERACTIONS BETWEEN SIGNALING AND ADHESION MOLECULES

Signaling and adhesion molecules frequently function cooperatively in sequential cascades to enhance the specificity of cell adhesion. Three examples of how these cooperative interactions facilitate blood cell responses are described next.

Platelet Adhesion and Aggregation

At sites of blood vessel injury in the arterial circuit, platelets rapidly tether to and then translocate or roll along the damaged vessel through reversible interactions of GPIb–IX–V receptors with immobilized vWF exposed in the subendothelial matrix of injured vessels (Fig. 10-2). These interactions are facilitated by arterial flow, perhaps because of complex effects of high wall shear stresses on the lifetimes of bonds between GPIb and vWF. An important feature of this initial reversible adhesive event is that prior activation of the platelets is not required. After adhesion, however, the interaction of immobilized vWF with GPIb receptors triggers intracellular signals that lead to platelet activation. These signals synergize with those produced by engagement of the collagen receptor GPVI. Platelet activation, in turn, increases the affinity of platelet integrins for collagen and fibronectin, which stabilizes adhesion. Binding of these ligands transduces signals that propagate further activation responses such as spreading, secretion of granule contents, and recruitment of additional platelets through cell–cell contact mediated by binding of fibrinogen to activated $\alpha_{IIb}\beta_3$ integrins. This adhesion cascade allows unstimulated platelets to home to the site of vascular injury and then be activated by locally generated mediators.

Neutrophil Rolling, Spreading, and Migration

Near sites of extravascular bacterial infections, neutrophils first tether to and roll on the endothelial surface of venules through the interactions of selectins with cell-surface carbohydrate ligands (Fig. 10-3). Little, if any, leukocyte adhesion occurs in nearby arterioles. Neutrophil rolling on the endothelium occurs under shear forces, just as platelets adhere to subendothelial matrix under shear forces, although the shear flow in postcapillary venules is lower than that in arterioles. Rolling requires a balance between the formation of selectin–ligand bonds at the leading edge of the cell and the dissociation of bonds at the trailing edge of the cell. Whereas shear forces affect the lifetimes of selectin–ligand bonds; lower forces prolong lifetimes (catch bonds), higher forces shorten lifetimes (slip bonds). Catch bonds help explain why a minimum shear force is required to support leukocyte rolling, particularly through L-selectin. Just as the initial adhesion to vWF does not require prior activation of platelets, selectin-mediated rolling does not require prior activation of neutrophils. Instead, locally generated inflammatory mediators induce expression of E- or P-selectin

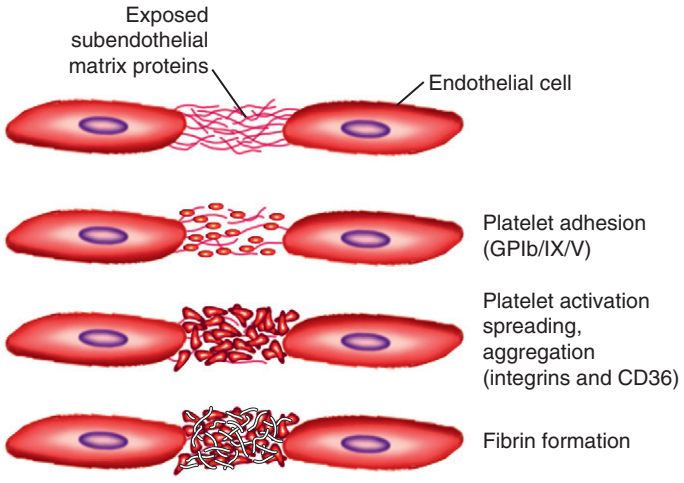

Figure 10-2 PLATELET ADHESION AND AGGREGATION. In response to arterial injury under high shear forces, platelets rapidly adhere to the subendothelial matrix of injured vessels. The initial contacts are made between glycoprotein Ib–IX–V (GPIb–IX–V) on platelets and von Willebrand factor (vWF) in the matrix. These molecular interactions help activate platelets, thereby increasing the affinity of several platelet integrins for other adhesive matrix proteins such as fibronectin, laminin, and collagen. GPVI further activates platelets by binding to collagen. CD36 also interacts with both collagen and thrombospondin. Fibrinogen cross-links activated platelets into aggregates by binding to $\alpha_{IIb}\beta_3$ integrins. The platelet plug then serves as an efficient surface for generation of thrombin and fibrin.

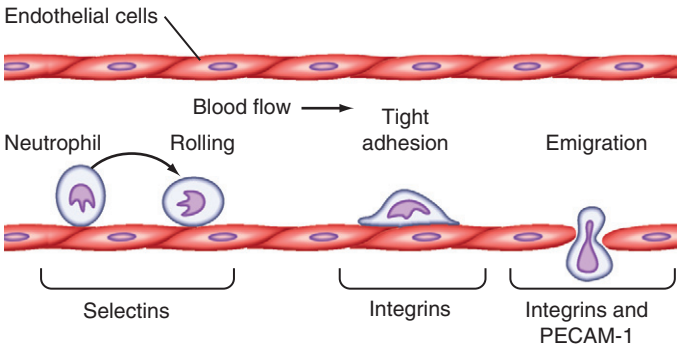

Figure 10-3 NEUTROPHIL ROLLING, SPREADING, AND EMIGRATION. At sites of tissue injury or infection, neutrophils first roll on the endothelial cells in postcapillary venules. These transient adhesive interactions are mediated by activation-induced transcription-dependent expression of E- or P-selectin on the endothelial cell surface. E- and P-selectin bind to carbohydrate ligands on the neutrophil. These molecular bonds can form under the shear forces in the venular circulation. The rolling neutrophils are then activated by locally generated inflammatory mediators that increase the affinity of β_2 integrins for immunoglobulin-like receptors such as intercellular adhesion molecule-1 (ICAM-1) on the endothelium. These bonds slow rolling and then promote firm adhesion to the endothelium. Neutrophil migration between endothelial cells into tissues at the site of infection requires disengagement of old adhesive bonds and formation of new bonds among integrins, platelet and endothelial cell adhesion molecule-1 (PECAM-1), and their respective ligands.

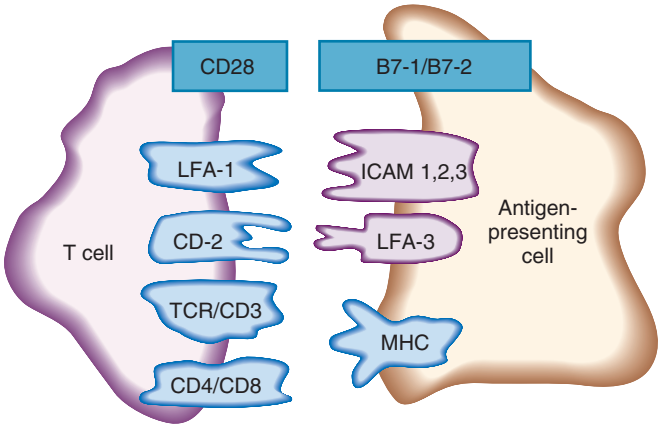

Figure 10-4 ADHESION BETWEEN T LYMPHOCYTES AND ANTIGEN-PRESENTING CELLS (APCs). The initial contact is mediated by the T-cell receptor (TCR), or CD3, which binds with low affinity but high specificity to a specific antigen presented by a major histocompatibility complex (MHC) molecule. Additional contacts, also of low affinity, are between CD4 (on helper cells) or CD8 (on cytotoxic cells) and MHC and between costimulatory molecules CD2 and leukocyte function-associated antigen-3 (LFA-3) and CD28 and CD80 (B7-1) and CD86 (B7-2). These interactions signal the T cell to increase transiently the affinity of the β_2 integrin LFA-1 for the immunoglobulin-like molecules intercellular adhesion molecule ICAM-1 on the APC. These bonds strengthen adhesion, and the costimulatory molecules transduce further signals to the T cell that cause increased gene transcription, proliferation, and cytokine secretion. Not shown is the redistribution of these adhesion molecules into different regions of the contact zone as adhesion strengthens. Additional signals result from binding of β_1 integrins on the T cell to adhesive proteins in the extracellular matrix.

on the endothelial cell surface. The requirement for activation of endothelial cells rather than leukocytes allows the latter to adhere to vessels only at the site of vessel inflammation. After being situated on the vessel wall through selectin-mediated contacts, however, the neutrophils become exposed to activators such as platelet-activating factor, a phospholipid signaling molecule, activated complement proteins, and IL-8, a potent chemoattractant cytokine or chemokine, both of which are presented on the surface of activated endothelial cells. These signals cooperate with others directed by engagement of selectin ligands and promote very slow rolling of neutrophils on the surface of activated endothelium. Neutrophil activation increases the affinity of β_2 integrins for immunoglobulin counterreceptors on the endothelial cell surface such as ICAM-1. Although flowing cells cannot form these bonds, neutrophils rolling on selectins can do so because of their slower velocities. The integrin–ICAM interactions further slow rolling and then arrest the cells on the endothelium. The leukocytes then migrate, presumably because of disengagement of integrin–ICAM bonds and redistribution of integrins to the leading edge of the cell, where new bonds form. Interactions of leukocytes with JAMs and PECAM-1 and other molecules at interendothelial cell junctions facilitate transendothelial migration of the neutrophils into the underlying tissues. Adhesion of leukocytes to the endothelium disrupts cytoskeletal tethers to the endothelial cadherins; this disruption leads to dissociation of homotypical cadherin interactions that normally prevent passage of leukocytes. Both the integrin- and the PECAM-1–mediated adhesive events may signal cytoskeletal redistributions in leukocytes that enhance migration toward chemotactic molecules released in the vicinity of the infection. When leukocytes enter in the tissues, integrin recognition of ECM protein ligands may trigger secretion of proteolytic enzymes and production of superoxide anions, both required for optimal bactericidal function.

Adhesion of T Cells to Antigen-Presenting Cells

The initial engagement of T cells with antigen-presenting cells requires that the T-cell receptor (CD3) recognize antigen presented by the polymorphic domain of MHC molecules (Fig. 10-4). Subsequent interactions include the binding of CD8 or CD4 to MHC class I or II molecules, respectively, plus the binding of CD2 to LFA-3 and CD28 binding to B7 molecules. These molecular contacts are all of low affinity but are highly specific because they first require specific antigen presentation to the appropriate T cell. The combination of these binding events triggers inside-out signals that increase the affinity of LFA-1 ($\alpha_L\beta_2$), a β_2 integrin on T cells, for its ligand, ICAM-1 on antigen-presenting cells, strengthening and prolonging the length of time cells stably adhere. During this time, the T cell is further activated by a second or costimulatory signal delivered by T cell CD28 binding to B7 molecules expressed by antigen-presenting cells. Together these interactions drive TCR-induced gene activation (IL-2 production) and cell proliferation and differentiation into different effector T cells that exit the secondary lymph node and migrate to immune reactions (see Chapter 19 for detailed discussion of T cell–antigen-presenting cell activation).

The first principle of these three responses is that the initial adhesive event, although relatively limited, is highly specific. Thus, platelets bind to exposed subendothelial matrix in injured vessels, neutrophils bind to hyperadhesive endothelium near the site of infection, and T cells bind to cells presenting specific antigen in secondary lymph nodes. The second principle is that subsequent activation events strengthen cell adhesion and lead to further responses such as secretion, fibrin formation, cellular migration, and release of cytotoxic mediators or cell activation and proliferation. Activation often results from cooperative signaling by soluble agonists and by binding of ligands to adhesion receptors. Costimulation by multiple signals can amplify and provide specificity to cellular responses by mechanisms not always feasible for individual mediators. Thus, adhesion and cell signaling are highly interrelated processes.

The process of reversing cell adhesion, although less well understood, is equally important for the control of cell behavior. Some molecules such as the selectins can be proteolytically cleaved or internalized. The activation-induced increases in affinity of integrins and CD44 for their ligands are generally transient, but the mechanisms for return to the inactive conformation are obscure.

Table 10-6 Genetic Deficiencies in Adhesion Molecules

Molecule	Disease	Laboratory Finding(s)	Clinical Finding
$\alpha_{IIb}\beta_3$	Glanzmann thrombasthenia	Impaired platelet aggregation	Mucocutaneous bleeding
GPIb/IX/V	Bernard–Soulier syndrome	Impaired platelet adhesion to vWF	Mucocutaneous bleeding
β2 integrins	Leukocyte adhesion deficiency-1	Impaired adhesion of activated leukocytes to EC	Frequent infections
Selectin ligands	Leukocyte adhesion deficiency-2	Impaired fucose metabolism resulting in defective carbohydrate ligands for selectins, impaired rolling of leukocytes on venules	Frequent infections
β1, β2, β3 integrins	Leukocyte adhesion deficiency-3	Impaired platelet adhesion and aggregation and impaired adhesion of activated leukocytes to EC	Mucocutaneous bleeding and frequent infections

For abbreviations, see Table 10-1 footnotes.

ALTERED EXPRESSION OF ADHESION MOLECULES

The highly regulated nature of adhesive events by hematopoietic cells suggests that defects in or excessive expression of adhesion molecules may contribute to the pathogenesis of disease. A variety of clinical observations support this hypothesis.

Genetic Deficiencies in Adhesion Molecules

Genetic deficiencies in platelet adhesion receptors such as the GPIb complex (as in Bernard-Soulier syndrome) and the $\alpha_{IIb}\beta_3$ integrin (as in Glanzmann thrombasthenia) result in hemorrhagic symptoms similar to those in patients with thrombocytopenia (Table 10-6). Genetic deficiencies in the leukocyte β_2 integrins (as in leukocyte adhesion deficiency-1) are associated with frequent severe bacterial infections and a failure of neutrophils to enter the infected tissues. Similar symptoms are seen in patients with a congenital defect in fucose metabolism that prevents synthesis of the carbohydrate ligands for selectins (leukocyte adhesion deficiency-2). A recently identified set of patients has both hemorrhagic symptoms and life-threatening infections (leukocyte adhesion deficiency-3). The molecular mechanism is attributable to mutations in an intracellular protein kindlin-3, which binds to β1, β2, and β3 integrin cytoplasmic tails upon cell activation. These patients have normal levels of integrin surface expression (see Table 10-6).

Dysregulated Expression of Adhesion Molecules

Inappropriate expression of adhesion molecules has been implicated in thrombotic and inflammatory disorders and in tumor metastasis. For example, erythrocytes from patients with sickle cell anemia adhere to each other, to leukocytes, and to the endothelium, contributing to vasoocclusive crises. These adhesive events may reflect, in part, the expression of integrins and selectin ligands not normally found on mature erythrocytes. Inappropriate adhesion and activation of platelets on exposed atherosclerotic plaques may contribute to thrombosis and acute ischemic coronary artery syndromes. Dysregulated expression of selectins on the endothelium of ischemic blood vessels during myocardial infarction or shock may contribute to neutrophil-mediated tissue necrosis after reperfusion of the vessel. Mediators released while the neutrophils are adherent in the reperfused vessels may activate integrin function, strengthening adhesion and generating further signals that release destructive oxygen radicals and proteases within the vasculature. Finally, malignant cells appear to use molecules normally used for adhesion of blood cells to promote metastatic spread through interactions with platelets, endothelial cells, and extravascular matrix.

These examples underscore the importance of proper regulation of adhesion molecule expression in the physiology of blood cells.

CHAPTER 11

HEMATOPOIETIC CELL TRAFFICKING AND CHEMOKINES

Steffen Massberg, Alexander G. Khandoga, and Ulrich H. von Andrian

The mammalian immune system has evolved to prevent infection while preserving self-tolerance and restraining immune-mediated pathology. Accomplishing these tasks requires billions of motile cells that continually travel throughout the body. The migration profiles vary substantially among individual types of leukocytes. However, their distinct traffic patterns are not random but follow a precisely organized process that is essential for proper immune surveillance and serves to maximize the likelihood that leukocytes will encounter and eliminate or contain pathogens.

During differentiation in the bone marrow (BM) (innate immune cells and B cells) or thymus (naive T cells), leukocytes are equipped with characteristic repertoires of traffic molecules that enable and restrict their migration to certain microenvironments and tissues. For example, whereas naive lymphocytes are poorly responsive to inflammatory signals, but they migrate efficiently to lymphoid organs, innate immune cells and antigen-experienced lymphocytes can respond to inflammation-induced traffic cues, although at least some subsets also travel to noninflamed (lymphoid and nonlymphoid) target tissues.[1-4] Notably, not only mature leukocytes migrate from one tissue to another via the circulation or lymphatic systems; some hematopoietic stem cells (HSCs) and progenitor cells also travel continuously throughout the body.[5-13] The characteristic trafficking of each leukocyte subset is coordinated by adhesion molecules expressed on leukocytes and endothelial cells (see Chapter 10) and through chemoattractants and their receptors. Chemoattractants are generated in a target tissue and can be sensed by passing leukocytes that express the appropriate receptor. Leukocyte chemoattractants include a number of lipid mediators; microbial factors; and a variety of peptides, such as activated complement 5 (C5a) and members of the chemokine family. This chapter will discuss chemokines as master navigation signals for leukocyte trafficking and then focuses on specific trafficking pathways that direct discrete leukocyte subsets to distinct target tissues.

CHEMOKINES IN CONTROL OF LEUKOCYTE TRAFFICKING

Nomenclature and Structure of Chemokines

Chemokines (short for *chemo*tactic cyto*kines*) are critical messengers in the complex cellular communication network used by the immune system. At least 47 chemokines have been identified to date (Table 11-1).[14-20] The two major subclasses of chemokines are distinguished as CC- or CXC-chemokines, depending on the arrangement of two canonical cysteine residues within the conserved chemokine motif, which are either adjacent (CC) or separated by a single amino acid (CXC). The XC (XCL1 and XCL2) and CX3C chemokines (CX3CL1) constitute two additional structural subfamilies of chemokines. Most chemokines are secreted proteins of 67 to 127 amino acids, only CXCL16 and CX3CL1 possess a transmembrane domain, but also exist in a cleaved, soluble form. Traditionally, chemokines were grouped into functional subfamilies termed "inflammatory" chemokines, that are induced by inflammatory signals and control the recruitment of effector leukocytes in infection, inflammation, tissue injury and malignancies, and "homeostatic" chemokines that navigate leukocytes during hematopoiesis in the BM and thymus during initiation of adaptive immune responses in secondary lymphoid organs and in immune surveillance of healthy peripheral tissues (e.g., CCL19, CCL21, or CXCL12). However, many chemokines cannot be assigned unambiguously to one of these two categories and are therefore referred to as *dual-function chemokines* (e.g., CXCL16, CXCL9).

Chemokine Signaling Through G-Protein–Coupled Receptors

Chemokine messages are decoded through specific cell-surface G protein–coupled receptors (GPCRs) with seven transmembrane domains.[21-25] The human chemokine receptor repertoire identified at present consists of 20 different GPCRs (Table 11-2).[26] The tremendous specificity and plasticity observed in leukocyte migration and anatomic distribution is largely owed to this system because each leukocyte subset expresses a distinct repertoire of chemokine receptors and each chemokine receptor can bind different sets of chemokines with various binding affinities.[27,28] Chemokine receptors function as allosteric molecular relays where chemokine binding to the extracellular portion modifies the tertiary structure of the receptor. This allows the intracellular domain of the engaged receptor to bind to and activate heterotrimeric G proteins. In response, the activated G proteins exchange guanosine 5′-diphosphate (GDP) for guanosine 5′-triphosphate (GTP) and in the process dissociate into Gα and Gβγ subunits. The dissociated Gβγ subunits mediate most chemokine-induced signals by activating different phosphoinositide-3-kinase (PI3K) isoforms, which in turn lead to the formation of phosphatidyl-3,4,5-triphosphate (PIP_3). PI3K and its product PIP_3 then translocate to the pseudopod at the leading edge of migrating leukocytes, where they colocalize with the small GTPase Rac.[29-32] PIP_3 activates Rac through specific guanine nucleotide exchange factors (GEFs).[33,34] Rac in turn acts through the downstream effectors p21-activated kinase (PAK) and the Wiskott-Aldrich syndrome protein (WASP) homologue WAVE, that stimulate actin-related protein (Arp) 2/3. Together, this process induces focal cytoskeleton polymerization, which is required for the development and forward extension of the pseudopod, a critical step in leukocyte chemotaxis.[35] The importance of PI3K-dependent signaling for leukocyte chemotaxis is evidenced by the lack of migration of myeloid leukocytes to chemokines in mice lacking PI3Kγ.[36-41] Notably, though, distinct signaling pathways or at least other PI3K isoforms appear to be involved in the trafficking of different subsets of immune cells. For example, whereas neutrophil and B-cell migration requires PI3Kδ, T-cell chemotaxis is not impaired in PI3K-deficient mice but depends on the Rac guanine exchange factor DOCK2.[42-48]

Termination of Chemokine Signaling

Different pathways have been identified that can terminate chemokine signaling through their GPCRs. The Gα subunit possesses an intrinsic GTPase activity to hydrolyze GTP. In a negative feedback loop, this GTPase activity allows the Gα subunits to reassociate with the Gβγ subunits, thereby restoring the heterotrimeric G protein to its inactive state. In addition, another class of molecules, known as

Table 11-1 Chemokines and Chemokine Receptors

Chemokine	Chemokine Receptor	Physiologic Function	Tissue Expression	Disease Connection[¶]
		CC FAMILY		
CCL1 (I309)	CCR8*	Attracts monocytes, NK cells, and immature B cells as well as DCs	Lung, skin, synovial fluid, brain	Asthma, COPD, atopic dermatitis, juvenile arthritis, cancer, MS
CCL2 (MCP-1)	CCR2* DARC/Duffy[§] D6[§]	Recruits monocytes, memory T cells, and DCs	Lung, kidney, joint, large arteries, intestinum, skin, brain, lymphatic endothelium	Asthma, glomerulonephritis, rheumatoid arthritis, osteoarthritis, atherosclerosis, inflammatory bowel disease, psoriasis, bacterial and viral meningitis, diabetes, HIV infection, pulmonary tuberculosis, cardiomyopathy in human Chagas disease, HBV clearance, HCV severity
CCL3 (MIP-1α)	CCR1* CCR5* D6[§]	Attracts eosinophil, basophil, monocyte, and T cell	Lung, joint, intestinum, brain, lymphatic endothelium	Asthma, rheumatoid arthritis, osteoarthritis, inflammatory bowel disease, bacterial meningitis, MS
CCL3L1 (MIP-1αP)	CCR1* CCR3* CCR5* D6[§]	Attracts lymphocytes to sites of infection or tissue damage	Lymphatic endothelium	Co-receptor for HIV, various infectious diseases, including chronic hepatitis and Kawasaki disease
CCL4 (MIP-1β)	CCR5* D6[§]	Attracts NK cells, monocytes, and a variety of other immune cells	Joint, brain, lymphatic endothelium, tear fluid, vessels, skin	Major HIV-suppressive factor produced by $CD8^+$ T cells; involved in rheumatoid arthritis, osteoarthritis, bacterial meningitis, dry eye syndrome, dermatomyositis, psoriasis
CCL4L1 (MIP-1β2)	CCR5* D6[§]	Similar to CCL4	Lymphatic endothelium, skin	HIV infection, psoriasis
CCL5 (RANTES)	CCR1* CCR3* CCR5* DARC/Duffy[§] D6[§]	Chemotactic for T cells, eosinophils, and basophils; recruits leukocytes into inflammatory sites; induces the proliferation and activation of NK cells	Lung, kidney, lymphatic endothelium, skin, joint, large arteries	Asthma, glomerulonephritis, allergic rhinitis, atopic dermatitis, SLE, rheumatoid arthritis, MS, HIV infection, hepatitis C infection, sarcoidosis, atherosclerosis, diabetes
CCL7 (MCP-3)	CCR1* CCR2* CCR3* CCR5[†] D6[§]	Attracts monocytes Regulates macrophage function	Lymphatic endothelium, macrophages, some tumor cell lines	HIV infection, MS
CCL8 (MCP-3)	CCR1* CCR2* CCR3* CCR5[†] D6[§]	Chemotaxis and activation of mast cells, eosinophils, and basophils; recruits monocytes, T cells, and NK cells; potent inhibitor of HIV-1 by virtue of its high-affinity binding to the receptor CCR5	Lymphatic endothelium, skin, stromal cells	HIV infection, MS, atopic dermatitis
CCL11 (eotaxin)	CCR2[†] CCR3* CCR5* CXCR3A[‡] CXCR3B[‡] DARC/Duffy[§] D6[§]	Recruits eosinophils, basophils, monocytes, and T cells	Lung, intestinum, lymphatic endothelium, skin, large arteries	Asthma, inflammatory bowel disease, atopic dermatitis, myocardial infarction, MS
CCL13 (MCP-4)	CCR1* CCR2* CCR3* DARC/Duffy[§] D6[§]	Induces chemotaxis of monocytes, eosinophils, T lymphocytes, and basophils	Lung, large arteries, brain, kidney, placenta, lymph nodes, spleen	Asthma, atherosclerosis, MS
CCL14 (HCC1)	CCR1* CCR5* DARC/Duffy[§] D6[§]	Activates monocytes	Kidney, heart, liver	Chronic renal failure, herpes simplex infection, HIV infection, hepatitis, amyloidosis, dilated cardiomyopathy
CCL15 (HCC2, MIP-1δ)	CCR1* CCR3*	Activates monocytes	Liver, small intestine, colon	MS, sarcoidosis, renal insufficiency, psoriasis, cirrhosis, hepatitis

Table 11-1 Chemokines and Chemokine Receptors—cont'd

Chemokine	Chemokine Receptor	Physiologic Function	Tissue Expression	Disease Connection[‖]
CCL16 (HCC4)	CCR1* CCR2* CCR5*	Chemoattractive for monocytes and lymphocytes	Liver, thymus, spleen	Drug-induced liver damage, angiogenesis
CCL17 (TARC)	CCR4* DARC/Duffy[§] D6[§]	Chemoattractive for lymphocytes	Thymus, DCs, endothelial cells, keratinocytes, fibroblasts, skin	Autoimmune diseases, SLE, allergy, asthma, pulmonary fibrosis, allergic dermatitis, atopic dermatitis, bullous pemphigoid, atherosclerosis, allergic rhinitis
CCL18 (PARC)	CCR3[†]	Chemoattractive for lymphocytes	Lung, lymphoid tissues	HIV infection
CCL19 (ELC)	CCR7* CCX-CKR[§]	Homeostatic chemokine controlling lymphocyte recirculation and homing, trafficking of T cells into thymus, T- and B-cell migration to secondary lymphoid organs	Spleen, lymph nodes, placenta, kidney, brain, lung	Asthma, atherosclerosis, allergic rhinitis, HIV infection, rheumatoid arthritis, pulmonary sarcoidosis, inflammatory bowel disease, renal disease
CCL20 (MIP-3 β, LARC)	CCR6*	Strongly chemotactic for lymphocytes, DCs, weakly attracts neutrophils	Mucosal lymphoid tissues, lymphocytes, lymph nodes, liver, appendix, fetal lung	Inflammatory bowel disease, pulmonary sarcoidosis, asthma, COPD, colitis, psoriasis
CCL21 (SLC)	CCR7* CCX-CKR[§]	Homeostatic chemokine, controls trafficking of lymphocytes in(to) secondary lymphoid-tissues	Spleen, lymph nodes, placenta, kidney, brain, leukocytes, liver	Cancer metastasis, melanoma, lymphoma, renal fibrosis, chronic hepatitis, cardiomyopathy
CCL22 (MDC)	CCR4* D6[§]	Recruits regulatory T cells, macrophages	DCs, macrophages	Autoimmune diabetes, pleural effusion, autoimmune encephalomyelitis
CCL23 (MPIF-1, SCYA23)	CCR1*	Highly chemotactic for naive T cells and monocytes; weakly chemotactic for neutrophils	Lung, liver, bone marrow, myeloid cells	Rheumatoid arthritis, *Bordetella* pertussis, fibrosarcoma, atherosclerosis, systemic sclerosis
CCL24 (Eotaxin-2)	CCR3*	Inhibits the proliferation of HPCs; recruitment of eosinophils	Thymus, spleen, intestine, activated monocytes and T cells	Asthma, ulcerative colitis, dermatitis, fibrosis, leukemia, certain types of neoplasia
CCL25 (TECK)	CCR9* CCX-CKR[§]	Chemotactic for thymocytes, macrophages, and DCs; controls T cell development	Thymus, liver, intestine	Inflammatory bowel disease, prostate cancer, primary sclerotic cholangitis
CCL26 (Eotaxin-3)	CCR3* CCR2[†]	Chemotactic for eosinophils and basophils	Lung, ovary, endothelial cells, heart	Allergic dermatitis, asthma, rheumatoid arthritis, allergic rhinitis, bullous pemphigoid
CCL27 (CTACK)	CCR10*	Homing of memory T lymphocytes to the skin	Gonads, thymus, skin	Dermatitis, psoriasis, mycosis fungoides
CCL28 (MEC)	CCR3* CCR10*	Drives mucosal homing of T and B lymphocytes; induces migration of eosinophils	Columnar epithelial cells in the gut, lung, breast, and salivary glands; colon	Atopic dermatitis, antimicrobial activity against *Candida albicans*, psoriasis, bullous pemphigoid, Hodgkin disease
		CXC FAMILY		
CXCL1 (GROα)	CXCR2* DARC/Duffy[§]	Recruitment of neutrophils; melanoma growth stimulating activity	Lung, skin, brain	ARDS, psoriasis, bacterial meningitis, MS, wound healing, melanoma, tumor genesis, angiogenesis, hemolytic transfusion reactions
CXCL2 (GROβ)	CXCR2* DARC/Duffy[§]	Chemotactic for neutrophils	Lung, blood, bone, bone marrow, brain, cervix, connective tissue, eye, intestine, kidney	ARDS, severe sepsis, septic peritonitis, autoimmune diseases, rheumatoid arthritis
CXCL3 (GROγ)	CXCR2* DARC/Duffy[§]	Controls adhesion and migration of monocytes	Lung, blood, adipose tissue	ARDS, Influenza, *Escherichia coli* infection
CXCL4 (PF4)	CXCR3B*	Chemotactic for neutrophils, fibroblasts, and monocytes; regulates T cell trafficking and B lymphopoiesis	Lung, liver, kidney, bone marrow, ovary	Putative antigen in HIT, thrombosis, wound healing, ARDS, liver fibrosis, arthritis, atherosclerosis, arterial hypertension, allergic dermatitis, HIV infection, cancer, metastasis

Continued

Table 11-1 Chemokines and Chemokine Receptors—cont'd

Chemokine	Chemokine Receptor	Physiologic Function	Tissue Expression	Disease Connection[¶]
CXCL5 (ENA-78)	CXCR2*	Neutrophil chemotaxis; modulates connective tissue remodelling	Lung, joint, blood	Bacterial pneumonia, rheumatoid arthritis, osteoarthritis
CXCL6 (GCP2)	CXCR1* CXCR2*	Chemoattractant for neutrophils	Adipose tissue, bladder, bone, connective tissue, eye, intestine, kidney, liver, lung, pancreas, placenta, prostate, spleen, uterus	Several types of malignancies (chondrosarcoma, leukemia, liver tumor, non-neoplasia, pancreatic tumor, uterine tumors, small cell lung cancer), tonsillitis, inflammatory bowel disease
CXCL7 (NAP-2)	CXCR2* DARC/Duffy[§]	Stimulates mitogenesis, synthesis of ECM, regulates glucose metabolism and synthesis of plasminogen activator	Platelets, monocytes, DCs, bronchial mucosa, brain	COPD, bronchial dysplasia, cancer, metastasis
CXCL8 (IL-8)	CXCR1* CXCR2* DARC/Duffy[§]	Chemoattractant for neutrophils; potent angiogenic factor	Lung, joint, intestinum, skin, brain, kidney, pancreas	ARDS, bacterial pneumonia, diffuse parabronchiolitis, rheumatoid arthritis, osteoarthritis, inflammatory bowel disease, psoriasis, bacterial meningitis, SLE, nephritis, acute pancreatitis, acute pyelonephritis, cancer, AIDS-related Kaposi sarcoma
CXCL9 (MIG)	CXCR3A* CXCR3B* CCR3[†]	Chemoattractant for T cells and NK cells	Skin, thyroid glands, synovia, lymphoid tissue, joint	Psoriasis, kidney disease, rheumatoid arthritis, inflammatory bowel disease, Sjögren syndrome, Hashimoto thyroiditis, Graves disease, ocular sarcoidosis, arterial hypertension, allograft rejection, cancer, cerebral malaria, inflammatory bowel disease
CXCL10 (IP-10)	CXCR3A* CXCR3B* CCR3[†]	Chemoattracts monocytes, macrophages, T cells, NK cells, and DCs	T cells, monocytes, neutrophils, kidney, larges arteries, intestinum, skin, brain	Hepatitis C, sarcoidosis, glomerulonephritis, atherosclerosis, inflammatory bowel disease, psoriasis, viral meningitis, MS, rheumatoid arthritis
CXCL11 (I-TAC)	CXCR3A* CXCR3B* CXCR7 CCR3[†]	Chemotactic for activated T cells	Liver, lung, kidney, brain, thyroid glands, intestine	COPD, pulmonary fibrosis, hepatitis C virus infection, nephritis, Sjögren syndrome, autoimmune encephalomyelitis, autoimmune thyroiditis, arthritis, inflammatory bowel disease, atherosclerosis
CXCL12 (SDF-1)	CXCR4* CXCR7*	Activates different leukocyte subsets; strongly chemotactic for lymphocytes; homeostatic chemokine directing the migration of hematopoietic cells from fetal liver to bone marrow and the formation of large blood vessels	Pancreas, spleen, ovary, small intestine, joint, tumor tissue, endothelium, hematopoietic tissue	Angiogenesis, carcinogenesis, metastasis, HIV-1 infection, atherosclerosis, acute myeloid leukemia, lymphoma, chronic myeloproliferative disease, type 1 diabetes, rheumatoid arthritis
CXCL13 (BCA-1)	CXCR5* CCX-CKR[§]	Selectively chemotactic for B cells	Liver, spleen, lymph nodes, gut	Lyme disease, SLE, rheumatoid arthritis, neurosyphilis, MS, myasthenia gravis, Sjögren syndrome, prostatic disease
CXCL14 (BRAK)	Unknown	Chemotactic for monocytes; potent chemoattractant and activator of DCs; can stimulate the migration of activated NK cells; inhibits angiogenesis	Many normal tissues, where its cellular source is thought to be the fibroblast	Cancer, liver failure, Alzheimer disease, Charcot-Marie-Tooth disease type 1A, angiogenesis, obesity
CXCL16 (SR-PSOX)	CXCR6*	Migration of T cells and NK cells	DCs, T cells, lymph nodes, spleen	Atherosclerosis, inflammatory bowel disease, chronic kidney failure
		CX_3C FAMILY		
CX3CL1 (fractalkine)	CX3CR1*	Chemoattractant for T cells and monocytes; patrolling of resident monocytes in the steady state	Endothelial cells	Inflammatory bowel disease, myocardial infarction, acute renal failure, end-stage renal disease, periodontal tissue, cirrhosis, Parkinson disease, atherosclerosis, cancer metastasis

regulators of G protein signaling (RGS), also modulates signaling through chemokine GPCRs. RGS are a large and diverse protein family initially identified as GTPase-activating proteins (GAPs) of heterotrimeric G-protein Gα-subunits.[49,50] At least some RGS can also influence Gα activity through either effector antagonism by competing with effector molecules for GTP-bound Gα-subunits or by acting as guanine nucleotide dissociation inhibitors (GDIs).[49] To date, more than three dozen genes have been identified within the human genome that encode proteins containing an RGS or RGS-like domain.

Fine Tuning of Chemokine Signaling by Chemokine Cleavage and Inactivation

In addition to termination of GPCR signaling, fine tuning of chemokine communication is also achieved by proteolytic cleavage and inactivation of chemokines, chemokine receptors, or both, further adding to the plasticity of the chemokine system. Proteases, such as dipeptidyl peptidase CD26, elastase, and the a disintegrin and metalloproteinase (ADAM) family, as well as matrix metalloproteinases (MMPs), have been implicated in the control of chemokine-mediated navigation of leukocyte trafficking.[51-54] The MMPs are a family of more than 20 enzymes with important functions in matrix degradation. They also act on chemokines to regulate varied aspects of inflammation and immunity.[55] The ADAM family of disintegrins and MMPs, which has been implicated in the shedding of adhesion receptors, including L-selectin, vascular cell adhesion molecule (VCAM), and junctional adhesion molecule A (JAM-A) (see Chapter 10), also modulates trafficking by cleavage of the chemokine CX3CL1. Other chemokines, such as CCL2 (MCP-1), CXCL10 (IP-10), and CXCL12 (stromal cell–derived factor-1 α [SDF-1α]), are cleaved and inactivated by MMP-2 and -9.[56-58] Apart from MMPs, proteases stored in neutrophil granules, particularly cathepsin G and elastase, inactivate chemokines, such as SDF-1α and its receptor CXCR4, that regulate not only the migration of mature leukocytes but also the mobilization and homing of immature HSCs.[59,60] Hence, proteases by means of their chemokine-modifying properties must be regarded as integral components in the control of trafficking of mature leukocytes and their precursors.

The expression of chemokines and their GPCRs, but also the termination of chemokine signaling (including chemokine and GPCR cleavage) within the local micromilieu, act together to tailor the trafficking of specific leukocyte subsets under steady-state conditions and during inflammatory diseases.

The remainder of this chapter gives an overview on trafficking for different leukocytes. In general, leukocyte trafficking can be classified into three distinct patterns of migration (1) **entry into tissues** from the circulation, (2) **migration within tissues,** and (3) **exit from tissues.** Each of these steps in leukocyte trafficking is discussed in the following sections.

LEUKOCYTE ENTRY INTO TISSUES

The emigration of leukocytes from the circulation is governed by (1) cell surface receptors that mediate the process of adhesion to the vascular endothelium (see Chapter 10) and (2) signaling molecules particularly chemokines, (see section above), which fine tune adhesion and control subsequent leukocyte migration.[29,61-66] The initial phase of leukocyte entry into tissues involves five distinct steps: (1) **leukocyte tethering and rolling** mediated by selectins (a family with three members, P-, E-, and L-selectin) that interact with specialized carbohydrate ligands on opposing cells (also see Chapter 10); (2) **firm leukocyte adhesion** mediated by the concerted action of chemokines and a group of leukocyte adhesion receptors, the integrins (e.g., β-2 integrins LFA-1 [CD11a/CD18], Mac-1 [CD11b/CD18], and α4 β1 integrin VLA-4) interacting with their endothelial ligands belonging to the Ig-superfamily (e.g., intercellular adhesion molecule 1 [ICAM-1], ICAM-2, and VCAM-1); (3) subsequent Mac-1– and ICAM-1–dependent **postadhesion strengthening and crawling;** (4) **transendothelial migration** mediated predominantly through adhesion receptors expressed on the endothelial cell contacts; and (5) subsequent **interstitial leukocyte migration** to their target site within the tissue. The adhesion receptors involved in leukocyte–endothelium interactions are discussed in greater detail in Chapter 10. The following sections therefore only give a brief overview of the molecular events relevant to each of the five steps involved in leukocyte accumulation.

Tethering and Rolling of Leukocytes

Initially, tethers are formed between leukocytes and endothelial cells through adhesion receptors that are characterized by the ability to rapidly bind their ligands with high tensile strength. The most important initiators of leukocyte tethering are selectins, expressed on leukocytes (L-selectin), endothelial cells (E- and P-selectin), and platelets (P-selectin). The most relevant selectin ligands are sialomucins that

Table 11-2 Chemokine Receptors

Receptor	Chemokine Ligands	Cell Types
	CC FAMILY	
CCR1	CCL3 (MIP-1α), CCL5 (RANTES), CCL7 (MCP-3), CCL14 (HCC1)	T cells, monocytes, eosinophiles, basophiles
CCR2	CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), CCL13 (MCP-4), CCL16 (HCC4)	Monocytes, dendritic cells (immature), memory T cells
CCR3	CCL11 (eotaxin), CCL13 (eotaxin-2), CCL7 (MCP-3), CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4)	Eosinophiles, basophiles, mast cells, Th2, platelets
CCR4	CCL17 (TARC), CCL22 (MDC)	T cells (Th2), dendritic cells (mature), basophiles, macrophages, platelets
CCR5	CCL3 (MIP-1α), CCL4 (MIP-1β), CCL5 (RANTES), CCL11 (eotaxin), CCL14 (HCC1), CCL16 (HCC4)	T cells, monocytes
CCR6	CCL20 (MIP-3 β, LARC)	T cells (T regulatory and memory), B cells, dendritic cells
CCR7	CCL19 (ELC), CCL21 (SLC)	T cells, dendritic cells (mature), antigen-experienced B cells
CCR8	CCL1 (I309)	T cells (Th2), dendritic cells
CCR9	CCL25 (TECK)	T cells, IgA^+ plasma cells
CCR10	CCL27 (CTACK), CCL28 (MEC)	T cells
	CXC FAMILY	
CXCR1	CXCL8 (interleukin-8), CXCL6 (GCP2)	Neutrophils, monocytes
CXCR2	CXCL8, CXCL1 (GROα), CXCL2 (GROβ), CXCL3 (GROγ), CXCL5 (ENA-78), CXCL6	Neutrophils, monocytes, microvascular endothelial cells
CXCR3-A	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Th1 helper cells, mast cells, mesangial cells
CXCR3-B	CXCL4 (PF4), CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)	Microvascular endothelial cells, neoplastic cells
CXCR4	CXCL12 (SDF-1)	Widely expressed
CXCR5	CXCL13 (BCA-1)	B cells, follicular helper T cells (T_{FH})
CXCR6	CXCL16 (SR-PSOX)	$CD8^+$ T cells, SK cells, memory $CD4^+$ T cells
CXCR7	CXCL12 (SDF-1), CXCL11 (I-TAC)	Tumor cell lines, activated endothelial cells, murine fetal liver cells
	CX_3C FAMILY	
CX_3CR1	CX3CL1 (fractalkine)	Macrophages, endothelial cells, smooth-muscle cells
	XC FAMILY	
XCR1	XCL1 (lymphotactin), XCL2	T cells, NK cells

BCA-1, B-cell chemoattractant 1; *CTACK*, cutaneous T cell–attracting chemokine; *ELC*, Epstein Barr virus–induced molecule 1 ligand chemokine; *ENA*, epithelial-cell-derived neutrophil-activating peptide; *GCP*, granulocyte chemotactic protein; *GRO*, growth-regulated oncogene; *HCC*, hemofiltrate chemokine; *IP-10,* interferon-inducible protein 10; *I-TAC*, interferon-inducible T cell alpha chemoattractant; *LARC*, liver and activation-regulated chemokine; *MCP*, monocyte chemoattractant protein; *MDC*, macrophage-derived chemokine; *MEC*, mammary-enriched chemokine; *MIG*, monokine induced by interferon-γ; *MIP*, macrophage inflammatory protein; *NK*, natural killer; *SDF-1*, stromal cell-derived factor-1; *SLC*, secondary lymphoid-tissue chemokine; *SR-PSOX*, scavenger receptor for phosphatidylserine-containing oxidized lipids; *TARC,* thymus and activation-regulated chemokine; *TECK*, thymus-expressed chemokine.

are decorated with oligosaccharides related to sialyl-Lewis^x, including P-selectin glycoprotein ligand (PSGL)-1 and the peripheral node addressin (PNAd). Selectin-mediated adhesive adhesion bonds that are formed in the bloodstream are transient and do not allow prolonged leukocyte arrest. As the bonds continuously dissociate at the cell's upstream end, new bonds form downstream, resulting in a characteristic slow rolling motion of the tethered leukocyte.

Firm Adhesion of Leukocytes

To undergo firm adhesion, the rolling cell must engage additional adhesion receptors belonging to the integrin family, particularly CD11a/CD18 (LFA-1) and the α4 integrins, α4β1 (VLA-4) and α4β7. However, whereas selectins are constitutively active, integrins first need to be activated to assume a high-affinity state that promotes efficient adhesion to endothelial ligands. Integrin activation is induced on leukocytes by chemoattractant signals that trigger a reversible change in integrin conformation (leading to enhanced ligand binding affinity) or in integrin clustering (enhancing avidity) or both.[22] Some (but not all) chemokines presented on the luminal surface of microvascular endothelial cells can trigger rapid integrin activation and efficiently induce leukocyte arrest. The retention and presentation of chemokines on the vessel endothelium is mediated through binding to glycosaminoglycans (GAGs) in the luminal glycocalix. Chemokines that are produced in the abluminal space can be transported across the endothelial monolayer to the luminal surface with the help of the Duffy antigen receptor for chemokines (DARC).[67]

Chemokines signal through the $G\alpha_i$ subfamily of large heterotrimeric G proteins to promote integrin activation. $G\alpha_i$ can be inhibited by pertussis toxin (PTX); consequently, intravital microscopy studies have shown that lymphocytes treated with PTX undergo normal tethering and rolling interactions in high endothelial venules in lymph nodes (LNs) and Peyer patches (PPs), but unlike control cells, the PTX-treated cells are unable to engage in integrin-dependent firm arrest. Chemokine receptor activation precipitates a cascade of intracellular signaling events, which (among other effects) trigger integrin

activation. This integrin activation involves proteins that impinge upon the cytoplasmic tail of integrins, including kindlins and talin. Binding of these adapter molecules to the cytoplasmic tails of the integrin α and β chains is critical to regulate leukocyte adhesion to integrin ligands, such as the binding and spreading of neutrophils on ICAM-1 and the complement C3 activation product iC3b.[68]

Postadhesional Leukocyte Crawling

Once arrested, the adherent leukocytes rapidly polarize and slowly migrate within the vessel in random directions.[69-71] This process is called *intraluminal crawling* and is thought to be essential for enabling leukocytes to find exit points within the vessel through which they can leave the vasculature.[29] Whereas neutrophils crawl only in inflammatory settings, a subset of monocytes crawl constitutively within noninflamed microvessels under steady-state conditions.[63,72,73] These "patrolling monocytes" are poised to provide immune surveillance via rapid tissue invasion into the extravascular space in case of damage and infection. After emigration, these cells can differentiate into macrophages or dendritic cells (DCs).[73,74] Interactions among ß2-integrins, LFA-1, and Mac-1 with endothelial ICAMs are required for intravascular crawling.[69,73,75]

Leukocyte Transendothelial Migration

The transendothelial migration or diapedesis is a critical event allowing leukocytes to cross the vascular wall and enter their target tissue. Two routes of leukocyte diapedesis have been described so far: a paracellular route that dominates most extravasation processes and a transcellular route reported for neutrophils and some T cells.[76-82] Both routes involve the action of apical and junctional endothelial ICAM-1 and, at least in some settings, VCAM-1. In inflammatory conditions, additional junctional endothelial ligands, such as ICAM-2, platelet endothelial cell adhesion molecule 1 (PECAM-1), vascular endothelial (VE)-cadherin, endothelial cell-selective adhesion molecule (ESAM), CD99, CD99L2, and JAM, can contribute to leukocyte diapedesis.[77,83-89]

Interstitial Leukocyte Migration

After penetration of the endothelial barrier, leukocytes move in the interstitium to their target sites within the tissue. This interstitial migration occurs along gradients of chemotactic agents, guiding them toward their destination.[90,91] This process is called *leukocyte chemotaxis* and depends on the ability of migrating cells to sense gradients of chemoattractants.[92-94] The spatiotemporal formation of chemokine gradients in the interstitial tissue is mediated by glycosaminoglycans, which bind chemokines using low-affinity interaction and control the site and durability of the soluble chemokine gradients.[95,96] The exact mechanisms involved in interstitial migration of distinct leukocyte subsets remain controversial.[97] Only recently, it has been reported that interstitial leukocyte migration involves integrin-independent flowing and squeezing.[98] Proteolytic enzymes (proteases) such as heparase, elastase, and MMPs (MMP-2 and MMP-9) seem to play a critical role in leukocyte interstitial migration because they are required for the degradation of the components of the basement membrane as well as of the extracellular matrix during leukocyte locomotion.[53,99]

All of these consecutive steps—(1) leukocyte tethering and rolling, (2) exposure to a chemotactic stimulus and firm arrest, (3) postadhesive strengthening and intraluminal crawling, (4) diapedesis, and (5) interstitial migration—are essential for leukocytes to enter lymphoid and nonlymphoid tissues and to migrate to sites of inflammation. Correspondingly, in patients with leukocyte adhesion deficiency syndrome, a genetic defect either in ß2 integrins (type 1) or in fucosylated selectin ligands (type 2), neutrophils cannot stop or roll, respectively; this syndrome is characterized by marked leukocytosis and frequent and severe soft tissue infections.[100-102]

The following sections discuss the mechanisms that control the entry of different subsets of leukocytes into their specific target tissues.

CHEMOKINE CONTROL OF LYMPHOCYTE HOMING TO SECONDARY LYMPHOID ORGANS

Migration of bloodborne lymphocytes to secondary lymphoid organs is the best-characterized example of leukocyte trafficking from the circulation into distinct target tissues.[2,4,103-108] Lymphocytes constantly survey secondary lymphoid organs, which include the spleen, tonsils, the appendix, PPs and LNs, to determine whether an antigen is present that poses a threat to the body. This information is provided to T cells by DCs, which collect and trap antigen and then present it to T cells together with costimulatory molecules and cytokines. Mature DCs that have captured antigen in peripheral tissues and some memory cells reach the LNs through afferent lymph vessels.[109-111] In contrast, circulating T and B lymphocytes gain access to LN and PP through specialized postcapillary microvessels lined with cuboid endothelial cells that are known as *high endothelial venules* (HEVs).[112-115] HEVs in different secondary lymphoid organs express distinct patterns of trafficking molecules to serve as tethering platforms for defined subsets of lymphocytes. For example, whereas HEVs in LN express PNAd, HEV in PP express mucosal addressin-cell adhesion molecule (MAdCAM-1). Other mucosa-associated lymphoid organs, such as mesenteric LN, express both MAdCAM-1 and PNAd. Although T and B lymphocytes are recruited by similar multistep cascades to home to secondary lymphoid organs, the role of individual traffic molecules is not necessarily identical even when both subsets interact with the same microvessel.[2]

Specific mechanisms control homing to different secondary lymphoid organs. To illustrate this, the following section gives an overview on two prominent examples of lymphocyte homing: (1) lymphocyte homing to LNs and (2) lymphocyte homing to the PPs patches of the gut.

Homing of T and B Lymphocytes in High Endothelial Venules of Lymph Nodes

The first step in the homing cascade in LNs is mediated by L-selectin/CD62L expressed on all lymphocytes, except effector/memory cells. PNAd, an O-linked sulfated core 1 carbohydrate moiety that is exclusively found in HEV, is the major endothelial L-selectin ligand.[116-120] Binding of L-selectin to PNAd initiates lymphocyte rolling in HEV and slows down and marginates the free-flowing lymphocytes.[2,66,119] Although the L-selectin-PNAd interaction is required, it is not by itself sufficient to promote firm leukocyte adhesion. The subsequent firm arrest of rolling T and B lymphocytes is mediated by the α4ß1 integrin, ß2-integrin CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), and ß7-integrin, which bind ICAMs, particularly ICAM-1 and ICAM-2; VCAM-1; or MAdCAM-1 on high endothelial cells.[119-124]

Chemokines that are presented in the lumen of HEV function as triggers of integrin activation.[125,126] On naive T cells, integrin activation is primarily mediated by CCL21 (also called SLC, TCA4, exodus 2, or 6-C-kine), which is constitutively expressed and secreted by HEV. The secreted chemokine is noncovalently bound to glycosaminoglycans on the surface of HEV, where it activates rolling lymphocytes through binding to CCR7, which is expressed on naive B and T cells. Another CCR7 ligand, CCL19 (also termed ELC or macrophage inflammatory protein [MIP] 3β), also supports T-cell homing to LN.[126] CCL19 is not expressed by high endothelial cells themselves; however, CCL19 and other chemokines are released by extravascular cells in LN or in tissues that discharge lymph to a local LN. Lymph-borne chemokines can be transported to the luminal aspect of HEV. Correspondingly, chemokines, including CCL2, CCL19, and CCL21, injected under the skin of mice accumulate on the luminal surface of the HEV in draining LN, where they promote integrin activation on rolling leukocytes bearing the cognate receptors.[127-129]

Endothelial heparan sulfate has been shown to be essential in controlling chemokine presentation on the endothelium, contributing to the recruitment of lymphocytes to LN.[130]

B cells use largely the same trafficking molecules as naive T cells to home to LN. However, B cell–HEV interactions are only moderately affected by the absence of CCR7 or its ligands.[131] Correspondingly, LNs of mice lacking CCR7 contain few T cells, but the B-cell compartment (and the memory T-cell compartment) is less affected.[132,133] Similar observations were made in *plt/plt* mice, which have a spontaneous genetic defect resulting in deletion of CCL19 and the HEV-expressed form of CCL21 (mice, unlike humans, have a second *ccl21* gene that is only expressed in lymph vessels), demonstrating that B cells are not absolutely dependent on CCR7 to adhere to HEV.[131] In fact, rolling B cells can be induced to arrest in HEVs by either CCR7 agonists or by CXCL12 (also called SDF-1α), the ligand for CXCR4.[134] An additional chemokine pathway involving CXCL13 (also called BLC) and its receptor CXCR5 has also been implicated in B-cell homing to secondary lymphoid tissues.[135] Of note, although B cells encounter several distinct integrin-activation signals in HEV, B-cell homing to LN is nonetheless less efficient than that of T cells. A likely reason is that the B cells express only approximately half the number of L-selectin molecules expressed on T cells, which greatly affects their ability to initiate the adhesion cascade in HEV.[115,136]

Homing in the High Endothelial Venules of the Peyer Patches

In HEVs of PP, similar homing mechanisms are encountered as described above for LNs. However, the levels of L-selectin ligands (which are immunologically distinct from PNAd) expressed by HEV in PP are considerably lower compared with LN.[137,138] As a result, L-selectin itself is not sufficient to initiate a successful homing cascade for most lymphocytes in PP.[137] Indeed, HEV in PP (and in mucosa-associated LN) additionally express MAdCAM-1, a ligand for the α4β7 integrin.[138-140] The α4β7 heterodimer, which comprises an α4 integrin chain (CD49d) linked to the β7 integrin chain, is expressed at low levels by naive T and B cells and is required for the successful homing of these cells in PP HEV.[137,140] After formation of an initial L-selectin-dependent tether, the α4β7-MAdCAM-1 pathway stabilizes and slows the rolling lymphocytes without requiring chemokine activation. After a chemokine signal has been transmitted, both α4β7 and LFA-1 become activated and jointly mediate firm arrest.[137]

Of note, α4β7 is strongly upregulated on gut-homing effector/memory lymphocytes but completely absent on skin-homing memory T and B cells; these differential levels of α4β7 integrin expression allow certain antigen-experienced lymphocyte subsets to acquire tissue selectivity.[141] The mechanisms underlying this specificity and plasticity of lymphocyte homing are addressed later. Similar to the case in LNs, chemokines are essentially involved in promoting integrin activation and allowing firm lymphocyte arrest in HEV of PP. Thus, CXCR4, CXCR5, and CCR7 have been implicated in B-cell homing, and CCR7 seems exclusively responsible for T-cell homing. Interestingly, although T and B cells are recruited across the same HEV in LNs, there is segmental segregation of T- and B-cell recruitment in PP. HEV supporting B-cell accumulation in PP are concentrated in or near B follicles and present CXCL13, but not CCL21, but T cells preferentially accumulate in interfollicular HEV (i.e., within the T-cell area), which express high levels of CCL21, but not CXCL13.

The above examples clearly show that each leukocyte must undergo a specific sequence of distinct molecular steps to arrest within microvessels. Notably, this sequence differs among different lymphoid and nonlymphoid tissues and between steady-state and inflammatory conditions. This explains why only certain leukocyte subsets gain access to lymphoid tissues and others are excluded. Granulocytes, for example, express LFA-1 and L-selectin but not CCR7. Consequently, although granulocytes can roll in HEV (via L-selectin), these leukocytes do not perceive an integrin-activating stimulus and therefore fail to accumulate in noninflamed LNs or PPs. Likewise, mature DCs express CCR7 and CD11a/CD18 but not L-selectin. Because these cells are thus incapable of rolling in HEV, they fail to home to noninflamed LN from the blood (although mature DCs readily access LN via afferent lymph). Hence, the GPCR-mediated integration activation step is critical for imparting specificity to the process of lymphocyte homing to LNs.

TRAFFICKING OF LEUKOCYTES FROM BLOOD INTO NONLYMPHOID TISSUES

General Principles of Leukocyte Trafficking to Nonlymphoid Tissues

As already outlined, naive lymphocytes migrate most efficiently to secondary lymphoid organs from which innate immune cells are excluded. However, both innate immune cells and subsets of lymphocytes can respond to inflammatory or activation signals by modulating the expression or activity of traffic molecules in a way that allows them to migrate to nonlymphoid tissues but also to inflamed lymphoid tissues. For example, in response to an inflammatory stimulus, granulocytes, including neutrophils, eosinophils, and basophils, are rapidly recruited to the affected site and provide the first line of defense. Thereafter, additional immune cells, including monocytes, DCs, and effector cells as well as memory lymphocytes, may be recruited. Essentially, all of these different recruitment events depend on distinct multistep adhesion cascades.

Many of the inflammation-seeking traffic molecules required for access to nonlymphoid tissues are shared by the different leukocyte subsets. The key receptors that initiate capture of neutrophils, monocytes, natural killer cells, eosinophils, and effector T and B cells at peripheral sites of injury and inflammation are the three selectins, the leukocyte-expressed L-selectin as well as P- and E-selectin, which are induced on both acutely and (in some settings) chronically stimulated endothelial cells.[142-146] In addition, leukocyte–leukocyte-interactions, mediated through PSGL-1 and L-selectin can also support accumulation of immune cells in inflamed tissues.[147-150] Subsequent firm arrest of leukocytes in nonlymphoid tissues involves integrins, including CD11a/CD18 (and its ligand ICAM-1 and possibly also ICAM-2), VLA-4 (and its ligand VCAM-1), as well as Mac-1 (and its ligand ICAM-1).[1,29,151] As discussed earlier for lymphoid tissues, chemoattractants, including chemokines and other GPCR agonists, such as formyl peptides, activated complement fragments (particularly C5a), and lipid mediators (e.g., PAF and LTB4), contribute essential integrin-activation signals for leukocytes at sites of inflammation. The molecular diversity and selective action of these different chemoattractants on distinct leukocyte subsets as well as their restricted temporal and spatial expression patterns provide a crucial mechanism for the fine tuning of cellular immune responses.[66,152,153]

Mechanisms of Tissue-Tropic Lymphocyte Trafficking

In most innate immune cells, the changes that are induced by activation signals are relatively uniform. In contrast, the migratory properties acquired by T and B lymphocytes in response to activation are diverse depending on the strength, the quality, and the context of the antigenic stimulus.[141] Specifically, antigen stimulation of naive lymphocytes results in the generation of effector and memory cells that express specific repertoires of trafficking molecules that guide them back to tissues containing the stimulatory antigen.[154-156] Thus, whereas a cutaneous challenge generates preferentially a skin-tropic memory response, oral stimulation induces preferentially gut-homing effector and memory cells.

Recent studies have shown that DCs play a critical role in fine tuning the tropism of lymphocytes. In addition to presenting antigen, DCs in different lymphoid organs are endowed with information indicating the tissue from which the antigen was obtained. DCs in

mucosa-associated lymphoid tissues (unlike those in other lymphoid organs) possess the enzymatic machinery to synthesize retinoic acid (RA) from vitamin A.[157] Exposure of activated T cells to RA induces the expression of gut-homing receptors (i.e., α4β7 and CCR9) and suppresses skin-homing molecules.[155,158] In the absence of RA, T-cell stimulation induces few or no gut-homing molecules but instead promotes the expression of P- and E-selectin ligands as well as CCR4, which are needed for homing to the skin. Additionally, when activated T cells are exposed to interleukin-2 (IL-12) and high levels of vitamin D3, which is physiologically induced by sunlight in the skin, they upregulate CCR10, the receptor for the epidermal chemokine CCL27.[159] This organ-specific information can reprogram and "imprint" the tissue-tropic memory cells as they differentiate from naive lymphocytes.[156]

Similar to T cells, B-cell subsets also express homing receptors that permit their selective trafficking to specific tissues. For example, distinct B-cell subsets produce the immunoglobulin isotype IgA that is present in secreted body fluids, including tears, breast milk, and mucus. IgA^+ B cells are characterized by their expression of CCR10.[160,161] The ligand for CCR10, MEC/CCL28, is expressed predominantly in mucosal tissues that secrete IgA.[162] Hence, CCR10 may function as a homing receptor that allows IgA-secreting B cells to migrate to tissues where IgA is required. A large subset among the IgA secreting B cells are those in the small intestine, which in addition to CCR10 express the gut-homing receptors, α4β7 and CCR9. When naive B cells are activated in the presence of intestinal DCs, they upregulate not only these two traffic receptors but also undergo class switching to IgA. This imprinting effect is dependent on RA, which is sufficient to induce gut-homing receptors, but must be combined with DC-derived IL-5 or IL-6 to promote IgA class switching.[158] At least 50 additional subtypes of lymphocytes have been characterized in human blood, and it is likely that multiple similar associations among homing receptors, immunologic effector function, and tissue specificity will be revealed in future.

MIGRATION OF HEMATOPOIETIC STEM CELLS TO THE BONE MARROW

Role of Adhesion Molecules for Hematopoietic Stem Cell Trafficking

The BM is the principal site of hematopoiesis in the adult body. Correspondingly, most HSCs are lodged in the BM cavity. Within the BM, maintenance of HSCs and regulation of their self-renewal and differentiation is thought to depend on the specific microenvironment, which has historically been termed the *stem cell niche* (see Chapter 12).[6,8,163-165] The central role of stem cell niches for HSC function has been recognized with the discovery that *Sl/Sl*^{d} (steel-Dickie) mice bearing a mutation in the gene encoding membrane-bound stem cell factor (SCF, also known as KIT ligand) show failure of BM HSC maintenance.[166] However, the exact localization as well as the composition of BM HSC niches and the molecular crosstalk that controls the retention of HSC within the niches are subject of intense ongoing research.[167-170]

Notably though, not all HSCs reside within the BM. In fact, it has been known for almost 4 decades that a small amount of hematopoietic precursors are also present in peripheral blood.[10-13] Bloodborne HSCs continuously migrate back to the BM cavity, presumably to fill any vacant stem cell niches.[13] Although the exact physiologic relevance of bloodborne HSCs remains to be determined, the intrinsic capacity of HSCs to home to the BM compartment is the prerequisite for successful clinical BM and stem cell transplantation. Homing of HSCs to the BM is a rapid process because murine and human progenitors injected intravenously are quickly cleared from the recipient circulation.[13,171,172] Similar to mature lymphocytes, HSCs and hematopoietic progenitor cells (HPCs) interact through a multistep adhesion cascade with BM microvessels.[7,172-177] Initially, HPCs tether and roll along BM microvessels.[178,179] This process involves α4β7 integrin on HSC/HPC, which binds VCAM-1, as well as E- and P-selectin on BM sinusoidal endothelial cells, which bind α(1-3)-fucosylated ligands, including CD44 and PSGL-1 on the surface of HPCs.[172] The subsequent firm arrest is mediated by activated α4β1 and VCAM-1, which is constitutively expressed in BM sinusoids. In addition to α4β1 integrin, the integrins α4β7, α5β1, and α6β1, CD44 as well as JAM-B have recently been implicated in HSC homing to the BM.[177,180-183] β1 integrin-mediated adhesion is important for HSC and HPC movement not only in adulthood but also during embryogenesis. Correspondingly, it has been shown that fetal HSCs/HPCs lacking β1 integrins form normally and differentiate, but they cannot colonize the FL, suggesting an essential role of β1 integrins in fetal HSC/HPC trafficking. In contrast to β1 integrins, the role of the β2-integrins LFA-1 (CD11a/CD18) and Mac-1 (CD11b/CD18) for HSC and HPC trafficking is controversially discussed. Although some studies have reported their involvement in HSC and HPC retention, others have indicated that the effect of β2 integrins becomes apparent only in synergy with α4β1.[184-186]

Role of Chemokines for Homing and Retention of Hematopoietic Stem Cells and Hematopoietic Progenitor Cells in the Bone Marrow

The chemokine CXCL12, the ligand for CXCR4 expressed by most hematopoietic cells, including HSCs, is thought to play a pivotal role in BM homing of HSC. BM endothelial cells (in addition to immature osteoblasts and other stromal cells) constitutively express and secrete CXCL12.[173,187-190] However, alternate pathways appear to exist because fetal liver–derived mouse HSCs home to the BM of adult recipients independent of CXCR4, and adult HSCs treated with a CXCR4 antagonist are still able to home sufficiently to the BM.[191,192] This indicates that HSCs may use different receptors or respond to distinct integrin-activation signals. In this context, the recent description of CXCR7, an alternate receptor for CXCL12, may explain some of the seemingly contradictory findings.[193]

Of note, the CXCL12/CXCR4 axis is not only involved in the homing process of HSCs to the BM but (among others) has also been linked to the retention of HSCs within stem cell niches and to the regulation of the maturation of more committed HPCs (particularly B-cell progenitor cells).[60,194-198] Correspondingly, disruption of the CXCL12/CXCR4 pathway leads to premature release of HPCs into the peripheral blood.[199,200] HPCs lacking CXCR4 accumulate in the circulation and fail to undergo normal lymphopoiesis and myelopoiesis, most likely because the cells do not receive the required maturation signals. Interestingly, upregulation of MMPs (see earlier discussion), which cleave and inactivate CXCR4 and CXCL12, has recently been implicated in HSC mobilization.[201-204] Mechanisms that modulate the CXCR4/CXCL12 axis are also thought to play a role in the coordinated mobilization of HPCs in response to cytokines that are used for this purpose in clinical practice.[59]

Regulation of Hematopoietic Stem Cell and Hematopoietic Progenitor Cell Homing in the Bone Marrow by the Nervous System

The nervous system has recently been shown to play a critical role in the regulation of the migration of HSCs and HPCs to and from the BM.[205-207] Signals from the sympathetic nervous system control the function of BM stromal cells, particularly osteoblasts, and regulate the attraction of stem cells to the BM niche by modulating stromal CXCL12 expression. Notably, trafficking of HSCs into and from the BM is not static but rather follows a physiologically regulated circadian rhythm. This circadian HSC migration is orchestrated in the nervous system through the rhythmic secretion of noradrenaline from nerve terminals in the BM, which leads to activation of the β_3-adrenergic receptor and downregulation of Cxcl12, the major BM chemoattractant for HSCs and HPCs. From a clinical point of view,

the timing of stem cell harvest or infusion may influence the yield or engraftment, respectively, and could affect the therapeutic outcomes.[206]

LEUKOCYTE MIGRATION WITHIN TISSUES

Trafficking Patterns of Lymphocytes

After a leukocyte has accessed a tissue, it must migrate to specific interstitial positions. As already discussed, homing typically requires that the bloodborne leukocyte completes a complex tissue- and subset-specific multistep adhesion cascade. One exception to this rule is the spleen, where most bloodborne lymphocytes can leave the circulation even when multiple traffic molecules are inhibited. However, chemokines are essential in all lymphoid organs, including the spleen, to guide the newly arrived lymphocytes to their proper position within the organ.

Multiphoton intravital microscopy was recently used as a tool to decipher the mechanisms that control the extravascular traffic patterns of homed lymphocytes within lymphoid and nonlymphoid tissues.[208-216] For example, imaging experiments have shown that T cells that have entered an LN move incessantly within the paracortex (T-cell area), where they query the resident DCs for the presence of antigens that activate their T-cell receptor. B cells that home to LN migrate to the more superficial B-cell–rich follicles, where they may detect antigens presented by follicular DCs. Activated B cells that encounter antigens then move to the margins of the B- and T-cell zones,[211] where they can receive help from antigen-specific CD4 T cells. Analogous specific microenvironments for T and B cells exist also in the other lymphoid tissues.

Migration of T Cells to T Zones within Secondary Lymphoid Organs

After homing to secondary lymphoid organs, T cells migrate within the T zones. They engage in highly motile ameboid movement (average speed, ~12 μm/min) and undergo multiple brief encounters with resident DCs.[217-219] A network of fibroblastic reticular cells guides T cells to the T zone and defines the limits of T-cell movement within this domain.[220,221] As a consequence of high T-cell motility, it has been estimated that every DC in an LN touches as many as 5000 naive T cells within 1 hour. When T cells encounter a specific antigen, they progressively decrease their motility, become activated, and form long-lasting stable conjugates with DCs. Finally, antigen-experienced T cells start to proliferate and resume their rapid migration while contacting DC only briefly.[219,222]

The positioning and high motility of T cells in the T-cell area is dependent on CCR7 and its ligands CCL19 and CCL21.[104,132,133,208,223,224] Both ligands are abundantly expressed in T zones by radiation-resistant stromal cells. Notably, ectopic expression of CCL21 induces the formation of LN-like structures in the pancreas of mice.[225] The expression of CCL19 and CCL21 but also of CXCL13, which attracts B cells to B cell follicles (see later discussion), by lymphoid stromal cells is strongly dependent on the cytokine lymphotoxin-α1β2 heterotrimers signaling via lymphotoxin β receptor.[226-228] Correspondingly, mice deficient in lymphotoxin have no morphologically detectable LNs or PPs.[229] CCL21 and CXCL13 have been shown to be transiently downregulated in activated or inflamed lymphoid tissues in a process controlled by the cytokine interferon-γ, alternating the positioning of T cells.[230,231]

POSITIONING OF B CELLS WITHIN SECONDARY LYMPHOID ORGANS

Similar to T cells, B cells enter secondary lymphoid organs from the blood to search for their specific antigens.[232] As previously outlined, the homing and entry of B cells into secondary lymphoid organs such as the LNs and PPs depends on chemokine–receptor interactions that finally result in firm adhesion of integrins on the surface of HEV. This adherence is followed by movement into lymphoid tissue.[134,230,233,234] After entering secondary lymphoid organs, the naive B cells migrate to B-cell–rich areas, termed B cell follicles. This migration depends on the presence of CXCR5 on the surfaces of B cells and the localized expression of CXCL13 by follicular stromal cells.[103,228,234] Follicular B cells are also highly motile migrating on a network of follicular DCs (FDCs), a process that is thought to be necessary to ensure optimal surveillance of the FDC for surface-displayed antigen. After a period of random migration within follicles, B cells that have not encountered a cognate antigen return to the circulation via the lymph or, in case of the spleen (also see later discussion), via the blood. In contrast, B cells that become stimulated by antigen relocate to the B-cell–T-cell boundary area to solicit help from T cells, which is necessary for further differentiation. To achieve this repositioning, activated B cells rapidly upregulate CCR7. This permits their chemotaxis toward CCR7 ligands expressed in the T-cell–rich zones of the secondary lymphoid organs.[211] Real-time imaging has been performed to further characterize the timing of this relocalization process. Antigen-engaged follicular B cells initially reduce their migration velocity upon antigen exposure. About 6 hours later, the activated B cells move toward the follicle border with the T-cell–rich zone and undergo highly dynamic interactions with helper T cells during the following several days.[211]

In the spleen, a subpopulation of B cells is lodged in the marginal zone (MZ) immediately adjacent to the marginal sinus that surrounds the white pulp cords. The exact extent to which chemokine-induced attraction and adhesion affect the positioning of MZ B cells is still unclear. However, recent studies indicate that the lodgment of B cells in the MZ is dependent upon interactions of αLβ2 and α4β1 on MZ B cells with their ligands (ICAM-1 and VCAM-1, respectively).[235,236] As with follicular B cells in LN, antigen encounter of MZ B cells causes their rapid repositioning to the B-cell–T-cell boundary area. The retention of naive B cells in the MZ and their relocalization to the B-cell–T-cell boundary area upon antigen encounter is thought to involve signaling through the phospholipid sphingosine-1 phosphate (S1P) and its receptor $S1P_1$.[237]

LEUKOCYTE EXIT FROM TISSUES

Although the coordinated role of adhesion molecules and chemokines governing lymphocyte entry into tissues has been examined in great detail, less is known about the exit of these cells from tissues. The final sections of this chapter discuss examples of emerging research on the diverse mechanisms that regulate exit of distinct leukocyte subsets from tissues.

Reprogramming Dendritic Cells to Exit Tissues Toward Secondary Lymphoid Organs

Lymphocyte homing remains without consequence unless lymphocytes encounter DCs that present their cognate antigen. DCs capture and present antigen to T cells more efficiently than any other antigen-presenting cell. In general, two routes of antigen delivery to LNs have been described to date: (1) antigenic material becomes lymph borne and is taken up by DCs that reside in the LN a priori and (2) antigen is acquired by DCs that reside in peripheral tissues and then transport the material to the draining LN. DCs constitutively patrol all tissues and engulf microorganisms, dead cells, and cellular debris. In the absence of inflammatory stimuli, the cells remain in an immature state that is only weakly immunogenic and often stimulates T-cell tolerance rather than activation. However, multiple signals associated with infection or tissue damage can induce DC maturation. Immature DCs express a variety of chemokine receptors, including as CCR1, CCR5, and CCR6, which are believed to result in the constitutive homing of immature DCs into tissues, particularly sites of inflammation, where ligands for these receptors are abundant.[4,109,238-240] After exposure to a maturation stimulus, such as Toll-like receptor

(TLR) agonists (e.g., LPS, bacterial lipoproteins, peptidoglycans, or CpG dinucleotides), which often originate from infectious pathogens,[241,242] whereas DCs lose CCR1, CCR5, and CCR6, expression of GPCRs for lymphoid chemokines, particularly CCR7 and CXCR4, is upregulated.[243] Lymphatic endothelial cells in peripheral tissues express CCL21, the ligand for CCR7.[244] The loss of chemokine receptors that keep the DCs within the tissue together with the increased expression of CCR7 results in the exit of the mature DCs via the lymphatic drainage system.[132,245] Recently it was shown that CCL21 is a more potent directional cue for DC migration than CCL19.[246] DC migration into the draining lymphatics requires also β2 integrin binding to ICAM-1 expressed by lymphatic endothelial cells. The JAM-A, which is expressed by DCs and the lymphatic endothelium, represses DC migration to LNs because the absence of JAM-A expression by DCs facilitates their migration to LNs.[111,247] Likewise, ß1-integrins, which mediate the interaction of DCs with extracellular matrix components, favor retention of DCs in the periphery.[111] While traveling to the draining LN, DCs upregulate the expression of molecules for efficient antigen presentation and T-cell stimulation and begin to generate chemokines and other cytokines that allow them to attract and stimulate T cells.[245,248,249]

Egress of Lymphocytes from Secondary Lymphoid Organs

When naive lymphocytes do not encounter antigen on antigen-presenting DCs after a period of random walk, they exit secondary lymphoid organs through efferent lymph vessels or, in case of the spleen, by directly returning to the blood. Several adhesion receptors have been implicated in the egress of lymphocytes into lymphoid sinusoids, including PECAM-1 (CD31), the mannose receptor, which interacts with L-selectin, and common lymphatic endothelial and vascular endothelial receptor 1 (CLEVER-1).[250]

We still have very limited information about the signals that determine the dwell time of lymphocytes in secondary lymphoid organs (≈12 to 24 hr for T cells). However, the recent observation that the egress of both T and B cells from LNs can be prevented by the immunosuppressant molecule FTY720 has revealed some of the principal mechanisms underlying lymphocyte egress. FTY720 is a synthetic derivative of myricin, a metabolite of the fungus *Isaria sinclairii,* which has been used in Chinese traditional medicine. FTY720 induces lymphocyte sequestration in LNs and causes profound lymphopenia. In animal models of transplantation and autoimmunity, FTY720 causes immunosuppression, and it has been shown to exert significant therapeutic effects in a placebo-controlled clinical trial of relapsing multiple sclerosis.[251-253] Although lymphocyte sequestration in LN and lymphopenia in response to FTY720 have been reported some time ago, the underlying molecular mechanisms were uncovered only recently.[108] Upon in vivo administration, FTY720 becomes rapidly phosphorylated and then binds to four of the five known S1P receptors, $S1P_1$and $S1P_{3-5}$.[103,254-256] Naive B and T cells express substantial levels of $S1P_1$, and it appears to be this receptor that plays a predominant role in lymphocytes egresses from lymphoid tissues into the efferent lymph vessels. Studies using gene-targeted mice have shown that T lymphocytes deficient in $S1P_1$ cannot exit secondary lymphoid organs (and in case of T cells, also the thymus).[257,258] Reports using FTY720 and $S1P_1$-selective agonists also supported a role for S1P–$S1P_1$ signaling in the regulation of lymphocyte egress from secondary lymphoid organs. Notably, $S1P_1$ receptors not only regulate lymphocyte exit from tissues but also modulate lymphocyte homing capacity.[114]

Whereas the sphingolipid S1P is abundant in blood and lymph, low levels of S1P are maintained within lymphoid tissues. This S1P gradient is established by the action of the S1P degrading enzyme S1P lyase.[259-261] Based on these findings, it has been proposed that S1P gradients between blood, lymphoid tissue, and lymph fluid together with cyclical ligand-induced modulation of $S1P_1$ on recirculating lymphocytes regulates lymphocyte egress and determines the lymphoid organ transit time of lymphocytes.[6,262] Indeed, recent observations support that concept by showing that $S1P_1$ on lymphocytes is downregulated in the blood, upregulated in lymphoid organs, and downregulated again in the lymph.[263] Notably, CD69, which is rapidly induced when T cells become activated, negatively regulates $S1P_1$ and thus promotes lymphocyte retention in lymphoid organs.[264,265]

Egress of Hematopoietic Stem Cells and Hematopoietic Progenitor Cells from Non-Marrow Tissues

Although the mechanisms that control HSC and HPC homing and egress from the BM are well investigated (see earlier discussion), little is known about the signals regulating the exit of HSCs and HPCs out of tissues other than the BM. HSCs and HPCs arrive in peripheral organs via blood but leave them predominantly via the draining lymphatics.[6,266] Interestingly, it has been shown that S1P and S1P receptors not only mediate egress of lymphocytes from LN but also control the egress of HSPCs from peripheral tissues.[6-8] Correspondingly, inhibition of S1P–S1P receptor signaling decreases the number of HSCs and HPCs in tissue-draining lymph because of impaired egress from the tissue. Stress signals that mimic an infection (induced by administration of a TLR4 agonist) reduce $S1P_1$ expression on HPCs, leading to the prolonged retention in peripheral organs. This prolonged tissue dwell time is necessary for HSC and HPCs to allow them to differentiate into immune cells on the spot. Tuning of HSC and HPC retention in peripheral tissues through the S1P– $S1P_1$ axis could support innate immune responses by fostering a local and versatile supply of effector cells.

FUTURE DIRECTIONS

This chapter has outlined three distinct modes of leukocyte trafficking, (1) **leukocyte entry into tissues** from the circulation, (2) **migration within tissues,** and (3) **exit from tissues.** The constitutive and inducible migration of leukocytes throughout the body is essential for lymphocyte development and warrants proper immune surveillance. The processes involved in leukocyte migration are tightly regulated by chemoattractants and adhesion molecules. Leukocyte migration is characterized by a tremendous level of plasticity and specificity because different leukocyte subsets express unique patterns of traffic molecules that enable their navigation to target tissues. Our expanding knowledge of the mechanisms that control leukocyte trafficking will likely influence the development of multiple therapeutic strategies, including stem cell mobilization; immunotherapy of cancer; and the treatment of tissue-specific autoimmune, inflammatory, and infectious diseases.

CHAPTER 12

DYNAMIC INTERACTIONS BETWEEN HEMATOPOIETIC STEM AND PROGENITOR CELLS AND THE BONE MARROW: CURRENT BIOLOGY OF STEM CELL HOMING AND MOBILIZATION

Shiri Gur-Cohen, Karin Golan, Kfir Lapid, Jonathan Canaani, Orit Kollet, and Tsvee Lapidot

The hallmark of hematopoietic stem cells (HSCs) is their motility and developmental program. The initial migration route of murine HSCs occurs during ontogeny in the embryo's yolk sac and the aorta–gonad–mesonephros (AGM) region[1] in which the first set of hematopoietic precursors develops. The initial wave of hematopoiesis is followed by the migration of HSC precursors to the fetal liver, where they undergo proliferation and differentiation to fetal blood cell lineages.[1,2] During the final stages of embryonic development, HSCs migrate from the fetal liver to the bone marrow (BM), guided by signals coming from the newly constructed bones. HSCs migrate via the blood circulation across the physical blood–BM endothelial cell barrier and extracellular matrices and finally home to their niches, supported by BM stromal cells. The murine BM stromal microenvironment, revealed as a negative regulator of hematopoietic stem and progenitor cells' (HSPCs) proliferation and differentiation via adhesion interactions, is believed to be part of the mechanism to preserve the quiescent HSPC pool in the BM while maintaining their migration and developmental potential.[3] Importantly, murine embryos that lack the chemokine stromal cell–derived factor-1 (SDF-1, also termed CXCL12),[4] which is highly expressed by many BM stromal cell types, or its major receptor CXCR4,[5] which is highly expressed by HSPCs, have multiple lethal defects, including lack of BM seeding and repopulation by fetal liver HSPCs. This abnormal phenotype reveals the essential role of the SDF-1–CXCR4 axis in HSC homing and repopulation during embryonic development. The adult BM is the major hematopoietic organ, where hematopoietic progenitor cells continuously replenish the blood with new maturing myeloid and lymphoid cells with a finite lifespan.[6] Bidirectional trafficking between the BM and the periphery, referred to as *homing, steady-state egress, stress-induced recruitment,* and *clinical mobilization,* is a hallmark of HSPC physiology.

This chapter discusses recent findings concerning the biology of HSPC homing and mobilization, emphasizing the major roles of the SDF-1/CXCR4 signaling cascade and the brain–bone–blood triad, which dynamically regulate stem cell migration and development.

HEMATOPOIETIC STEM AND PROGENITOR CELL HOMING

The prerequisite critical first step leading to successful clinical engraftment is homing of HSPCs to ablated BM of transplanted recipients, which is their predominant physiologic site of hematopoiesis.[7,8] Intravenously infused into the peripheral blood, HSPCs find their way to the BM and lodge there to initiate hematopoiesis and BM reconstitution.[8] This process requires the tropic SDF-1/CXCR4 guiding signal and firm adhesion and docking to the vascular sinusoidal wall followed by movement across the physical BM–blood endothelial cell boundary and extracellular matrix barrier toward the marrow cavity.[6,9] During the early stages of the homing process to the BM, murine HSPCs are directed preferentially to the trabecular-rich metaphysis of the femurs in nonablated mice at all time points from 15 minutes to 15 hours after transplant.[10] The homing process ends with selective access and anchorage of HSPCs to their specialized stromal niches within the BM. The choice of the BM microenvironment as the HSPCs' preferred residence is not casual. The BM is highly organized in a complex architectural and cellular structure, whereby HSPCs are localized and anchored in special stromal niches via adhesion interactions, providing signals that prevent their motility, proliferation, and uncontrolled differentiation. The murine HSPCs supporting stromal reticular niche cells express the highest levels of SDF-1, which is essential for stem cell quiescence and maintenance.[11,12] Dynamic signals produced by the brain–bone–blood triad via circadian rhythms and bone turnover, generate stress signals which coordinately turn the BM into the preferred environment for adult HSPCs.[8,13]

Studying Human Hematopoietic Stem and Progenitor Cell Homing: Use of Preclinical Immunodeficient Mice Models

To understand the complex mechanisms regulating human HSPC homing, functional preclinical animal models have been developed to study human stem cell engraftment. Human and murine SDF-1 are cross reactive and differ in only one amino acid, enabling engraftment of human HSPCs in transplanted immune deficient mice.[8] The severe combined immunodeficiency (SCID) mouse was one of the first immune-deficient models.[14,15] Additional murine models were developed throughout the years based on the initial SCID model, including the immunodeficient nonobese diabetes/SCID (NOD/SCID) mouse, which exhibits additional reduced immunity and was used to identify primitive human $CD34^+/CD38^-$ and $CD34^-/CD38^-$ SCID repopulating cells (SRC),[16,17] and the NOD/SCID/interleukin (IL)-$2R\gamma^{null}$ mouse, with further reduced innate immunity because of the lack of natural killer cell activity.[18] The homing of immature human $CD34^+$ cells to the recipient BM requires host preconditioning with sublethal total-body irradiation (TBI) or chemotherapy. These myeloablative regimens have been shown to induce a dramatic elevation of SDF-1 production and secretion by BM stromal cells,[19] disruption of the physical BM endothelium barrier,[20-22] and attraction of transplanted human $CD34^+/CXCR4^+$ cells to the BM microenvironment. Functional, preclinical immune-deficient murine models, which tolerate human HSPC xenografts, are important for understanding the mechanisms involved as well as identification of molecules participating in the biologic regulation of HSPC trafficking to and from the BM with clinical relevance.

Homing: Essential Role of the SDF-1–CXCR4 Axis

A major role in the regulation of HSPC homing is attributed to interactions between SDF-1 and its receptor CXCR4. Both human and murine BM stromal cells, including endothelial cells and

endosteal bone lining osteoblasts, express high levels of SDF-1. In parallel, circulating HSPCs express CXCR4 which allows them to be preferentially chemoattracted toward high levels of SDF-1 found in the BM, thus facilitating the homing process.[9] CXCR4-dependent homing is also observed in aging neutrophils, which express high levels of CXCR4 and migrate back to the BM across the mechanical barrier for their eventual apoptotic cell death.[23] Blocking of CXCR4 by neutralizing antibodies impaired homing of immature adult human $CD34^+$ progenitor cells to the BM of transplanted immunodeficient mice,[24,25] but genetic overexpression of CXCR4[26] or cytokine-induced increased surface expression of CXCR4[24,27] enhanced the homing capacity of transplanted human HSPCs. Given the important clinical challenge of improving HSPC engraftment and repopulation, upregulation of CXCR4 expression is a promising approach.[28]

Of interest, immature human $CD34^-/CD38^-$ SRC express low levels of CXCR4, have poor SDF-1 induced migration and cannot home when transplanted into the veins of immune deficient mice, hence requiring direct intra-bone transplantation.[29] Pre-incubation of $CD34^-/CD38^-$ cells on a murine stromal cell line induces $CD34^+$ expression on these cells and as a result improves their repopulation potential.[29]

The murine stem cell niche contains a rare population of reticular Nestin-positive mesenchymal stem cells (MSCs), which express the highest levels of SDF-1 in the BM microenvironment and form a niche for most HSCs.[11] Depletion of Nestin-positive stromal supporting niche cells results in defective hematopoiesis and reduced homing of transplanted HSPCs to the BM, demonstrating the crucial role of SDF-1 in homing of HSPCs.[11] Homing of human $CD34^+$ progenitors is largely regulated by the bioavailability of the SDF-1 guiding signal in the BM cavity. Functional, noncleaved SDF-1 is translocated from the blood circulation to the BM tissue through endothelial cells, which also express CXCR4[30] (as well as CXCR7, another SDF-1 receptor[31]). Once SDF-1 is bound to its receptor on the surface of the endothelial cell, it is internalized and transcytosed via clathrin-coated pit vesicles. The increase in SDF-1 levels in the BM functionally enhances the homing capacity of transplanted human $CD34^+$ progenitors to the BM of NOD/SCID mice.[30]

Dynamic changes in BM SDF-1 and CXCR4 levels affect HSPC homing. BM progenitor cells from mobilized individuals home better compared with nonmobilized BM progenitor cells because of elevated levels of CXCR4.[32] Prostaglandin E_2 (PGE_2), known to act through cAMP-mediated regulation of the Wnt signaling pathway to control HSC self-renewal and proliferation in-vivo,[33,34] is also capable of improving the homing efficiency of human and murine progenitor cells because of upregulation of surface CXCR4 expression,[28,35] resulting in consequently improved engraftment.[28] Enhanced CXCR4 expression as well as inhibition of SDF-1 degradation is important to enable a stable chemotactic response, directing the homing of HSPCs to the BM. Indeed, inhibition of the dipeptidyl peptidase CD26, a membrane-bound extracellular serine-protease with SDF-1 cleavage activity, improves homing to the BM and the engraftment potential of murine HSPC[36] and human $CD34^+$ SRC in transplanted immune-deficient recipients.[37,38] SDF-1 bound to CXCR4 was also found to enhance the expression of CD9, a member of the tetraspanin family of proteins expressed on primitive human $CD34^+/CD38^{-/low}$ and the more mature $CD34^+/CD38^+$ progenitor cells. Blockage of CD9 activity in immature human cord blood $CD34^+$ progenitors inhibits SDF-1–mediated migration, as well as conferring enhanced adhesion to fibronectin and endothelial cells. Moreover, CD9 blockage also impaired $CD34^+$ progenitor cell homing to the BM and spleens of transplanted NOD/SCID mice.[39]

Another important cytokine regulating progenitor cell homing is stem cell factor (SCF, c-Kit ligand), which plays an important role in hematopoiesis.[40] In contrast to immature cord blood $CD34^+/CD38^-$ cells, which home successfully to the murine BM and spleen, mature cord blood $CD34^+/CD38^+$ cells home poorly unless prestimulated with cytokines, such as SCF in vitro, for 1 to 2 days.[29] Prestimulation of human or murine HSPCs with SCF improved their in vivo homing abilities through increased migration and adhesion via very late antigen 4 (VLA-4) and VLA-5 integrins.[24,40,41] Moreover, the homing of murine progenitor cells to the BM of mice deficient in P- and E-selectin is impaired,[42] demonstrating the pivotal role of adhesion interactions for proper homing, allowing HSPCs rolling on BM endothelium and attachment to their stromal supportive niches.

Interestingly, SDF-1 is not the only chemoattractant factor in HSPC homing. The chemoattractant lipid sphingosine-1-phosphate (S1P) and ceramide 1-phosphate (C1P) were shown recently to have a role in inducing murine HSPCs homing to the BM by increasing progenitor adhesion to stromal cells.[43] The adhesion molecule CD44, expressed by murine and human HSPCs, is required for cell spreading and adhesion to hyaluronan and osteopontin, both of which are expressed by blood vessel walls and along the endosteum.[10] Blocking of CD44 prevents homing of immature human $CD34^+$ cells to the BM and spleen of NOD/SCID mice.[9,44] The importance of CD44–hyaluronan interaction in enhancing HSPC homing is further supported in physiologic conditions, showing that murine HSPCs home preferentially to the metaphysis of nonirradiated recipients, a process mediated by hyaluronan expression on endothelial cells in this area.[10] Changing the glycosylation of CD44 on MSC allows their interaction with selectins and navigation of human MSC to the murine BM.[45] Homing of murine and human HSPCs to the endosteal surface of the BM followed by their lodgment and engraftment also requires active sensing of calcium levels,[46,47] demonstrating the interplay between bone turnover and HSPC trafficking.

Taken together, manipulation of SDF-1 levels in the target organ and CXCR4 on the transplanted stem cells can be used to navigate stem cells in vivo to their target organs. Enhanced SDF-1 production by BM stromal cells after host preconditioning, crossing the blood–BM barrier and activation of the adhesion machinery are required for HSPC attraction and attachment to the BM supporting niches, allowing their subsequent self-renewal and differentiation.

RETENTION OF HEMATOPOIETIC STEM AND PROGENITOR CELLS IN THE BONE MARROW

After HSPCs home to the BM, they lodge at specialized niches, where they subsequently reside and contribute to ongoing hematopoiesis. The BM is highly organized in a complex architectural and cellular structure, where HSPCs are localized and anchored in stromal niches that prevent their motility, proliferation, and differentiation. Primitive murine HSPCs preferentially localize to endosteal regions rather than the central marrow along the bone shaft[48,49] and predominantly in the trabecular-rich metaphysis, which is also rich in blood vessels.[10] Retention at those BM niches is important for the support and maintenance of HSPCs,[50] and various cell types have been demonstrated to fulfill this supportive function in mice, including osteoblasts,[51,52] CXCL12-abundant reticular (CAR) progenitors adjacent to vascular cells,[12] reticular sinusoidal endothelial cells,[53,54] and Nestin-positive pluripotent MSC.[11] CAR and Nestin reticular progenitor cells have been shown to highly express various genes that are essential for HSC retention, such as SDF-1, SCF, vascular cell adhesion molecule 1 (VCAM-1), osteopontin, and angiopoietin-1.[11,12] In humans, reticular $CD146^+$ mesenchymal progenitors were identified as HSPC supporting cells,[55] and with similarity to mouse MSC, have been shown to express Nestin.[56] Whereas depletion of murine BM niche cells results in loss of HSPCs,[11,54,57,58] their increase is accompanied by higher HSPC numbers.[11,51] For example, increased numbers of osteoblasts caused by parathyroid hormone (PTH) administration or osteoblast-specific constitutively-active parathyroid hormone-related protein (PTHrP) receptors expand murine HSCs via Notch signaling.[51] Interestingly, preliminary results indicate that basic fibroblast growth factor (FGF2), a downstream mediator of PTH, expands HSCs by upregulating membrane bound SCF on stromal cells and c-Kit expression on HSPCs and downregulating SDF-1 expression by stromal cells.[59]

Apart from the current concept of HSC-supporting niche cells, another less established concept is the metabolic niche.[60] HSCs are predominantly located in hypoxic regions in the BM[61,62] and preferentially use glycolysis over mitochondrial oxidative

phosphorylation to meet their energy demands.[63] Thus, it is not surprising that balanced levels of the hypoxia-induced transcription factor hypoxia-inducible factor 1α (HIF-1α) are crucial for HSC function.[64] It was long hypothesized that mutual interactions among HSCs and their stromal supporting cells exert inhibitory feedback on proliferation and differentiation, keeping HSCs dormant in a nonmotile mode.[3,65] One such important interaction is mediated via angiopoietin-1 expression by BM osteoblasts and Tie-2 expression by HSCs, triggering cell cycle arrest as well as tight adhesion required for retention.[66] Thus, interference with the adhesion interactions may lead to their loss of function and mobilization. For example, conditional deletion of CXCR4[12,67] or SDF-1[68] leads to increased cycling and exhaustion of the stem cell pool, as well as loss of retention and protection from DNA-damaging agents. Deficiency in the cell cycle regulator CDC42 also results in increased cycling, impaired homing and retention, and massive mobilization.[69] Robo4 is predominantly expressed by murine HSCs, and mice that lack Robo4 expression exhibit reduced retention of HSCs, correlating with poor repopulation capacity.[70] Annexin2, which is expressed by murine HSPCs, assists in localizing to the endosteum by binding to SDF-1; therefore, transplantation of Annexin2-deficient HSPCs results in impaired engraftment.[71] It should be noted that homing and retention may be regulated by different mechanisms. In other words, a stem cell may home and reach the BM, but as long as it is not retained, successful engraftment is not achieved. For example, HSPCs that lack the G protein Rac1, calcium-sensing receptor or the guanine nucleotide exchange factor Vav-1 home normally but demonstrate impaired localization to the endosteum or to Nestin-positive MSCs, resulting in poor repopulation.[46,72,73] Inhibition of Rac1 also causes mobilization of HSPCs because of loss of retention.[72] Because adhesion interactions are crucial for retention of HSPCs in their BM niches, targeting these molecules is expected to induce mobilization. Indeed, administration of neutralizing antibodies to the integrin VLA-4,[74] which is expressed by HSPCs, or to its receptor VCAM-1,[75] which is expressed by the BM stroma, induces HSPC mobilization. Mice deficient in each of these adhesion molecules have higher numbers of circulating HSPCs.[76,77] The major adhesion molecule CD44 is an important player in homing and engraftment of HSPCs, assisting in localizing to hyaluronan-rich regions in the BM.[44] Thus, whereas CD44 blockage leads to HSPC mobilization,[78] mice that are devoid in one of the hyaluronan synthases show reduced lodgment of transplanted HSPCs to the endosteum.[10] It is therefore not surprising that breakdown of adhesion interactions is an integral part of mobilization mechanisms, induced by granulocyte colony-stimulating factor (G-CSF) or AMD3100 administration. SDF-1, which is essential for quiescent HSC retention and function is downregulated in the BM following repetitive G-CSF stimulations[79,80] or rapid AMD3100 treatment[81] as discussed later in this chapter. Of note, genes that are necessary for retention are downregulated in Nestin-positive MSCs after administration of G-CSF or agonists to β-adrenergic receptors, leading to detachment of HSPCs and allowing their enhanced egress.[11] Intriguingly, apart from adherence to osteopontin, which participates in murine HSPC lodgment at the endosteum region,[82] HSC proliferation is also negatively regulated by ostepontin,[82,83] demonstrating an inhibitory feedback role for retention in the niche. Retention of HSPCs in the BM is monitored by the endothelial BM–blood barrier. Although the levels of HSPCs in the circulation and spleen are similarly distributed in murine parabiotic partners (pairs of mice with connected blood vessels and a shared circulation), the BM HSPCs are mostly of host origin because of the presence of the aforementioned BM–endothelial barrier.[84] The low levels of partner derived HSPCs are dramatically increased after G-CSF mobilization, indicative of increased permissiveness of the barrier, enabling enhanced egress, which is followed by enhanced HSPC homing. Indeed, upon irradiation, chemotherapy, or G-CSF administration, the permeability of BM vasculature increases, thus disrupting the BM–endothelial barrier.[20,22,85] Altogether, proper retention of HSPCs at their BM niches is required for ongoing hematopoiesis and repopulation capacity, and the loss of retention is an integral part of mobilization physiology.

HEMATOPOIETIC STEM AND PROGENITOR CELL MOBILIZATION

Stress Signals and Extensive Hematopoietic Stem and Progenitor Cell Recruitment

Hematopoietic stem cells are maintained primarily in a homeostatic quiescent nonmotile state, mostly because of a complex tight regulation by the BM niche microenvironment.[3,12,86] Although most of the adult HSC compartment is located and preserved within the BM during homeostatic conditions, a small and rare population of HSPCs is constitutively released and circulates in the peripheral blood.[8] In the early 1960s, circulating HSPCs were described for the first time to have repopulation potential.[87] Psychologic stress such as anxiety,[88] as well as physiologic stress caused by bleeding, injury, inflammation, and DNA damage induced by radiation or chemotherapy, prompt dramatic changes that have a significant impact on HSPC fate.[8] These systemic and direct changes include the detachment of immature leukocytes from their anchored BM lodgment and initiation of cell cycle entry and progression followed by increased motility and massive recruitment of HSPCs to the circulation as part of host defense and repair.

The host immune response is associated with increased production of the myeloid cytokines granulocyte macrophage colony-stimulating factor (GM-CSF) and G-CSF, which trigger HSPC proliferation, differentiation, recruitment, and clinical HSPC mobilization.[89] Clinical mobilization protocols take advantage of the motile nature of HSPCs. Repetitive, once-daily G-CSF stimulations mimic stress conditions and provide proinflammatory signals. This cytokine induces HSPC detachment from their stromal niches and triggers massive accelerated progenitor proliferation and differentiation, involving a rapid increase in neutrophil counts and a gradual increase in HSPC numbers in the circulation, peaking between days 4 and 5 of G-CSF administration. Recruitment of HSPCs to the peripheral blood is not a passive release of proliferating HSPCs but rather an active process in which the impetus toward gaining motility is triggered by tightly regulated guiding signals, repressing the BM stromal inhibitory attachment machinery, which in turn allows mobilization of HSPCs to the circulation. HSPC mobilization is a complex multistep process involving the secretion of various cytokines and chemokines and the activity of proteolytic enzymes, which inhibit BM retention-inducing signals and increase the cells' trafficking capacity. The chemokine SDF-1 and its major receptor CXCR4 are essential components in the tightly regulated process of HSPC recruitment and mobilization. SDF-1 is produced by many BM resident cell types, including osteoclasts,[90] osteoblasts, endothelial cells,[30,81] reticular Nestin-positive MSCs,[11] and CAR stromal progenitor cells.[12] SDF-1 is a known powerful chemotactic factor for primitive human $CD34^+/CD38^-$ and murine $Sca\text{-}1^+/c\text{-}Kit^+/$ (SKL) cells enriched with repopulating HSCs.[91,92] An increase in SDF-1 levels in injured peripheral organs recruits $CXCR4^+$ progenitor cells from the BM reservoir and directs them to the site of injury.[93] Modulation in SDF-1 concentration also contributes to the delicate balance between hematopoiesis and directed motility: whereas low levels of SDF-1 induce proteolytic enzymes secretion by human $CD34^+$ progenitors (including matrix metalloproteinase-2 and 9; MMP2/9), directional migration, and proliferation, high levels induce internalization and desensitization of CXCR4,[94,95] progenitor cell quiescence,[96] and inhibition of cell motility. Thus, basal levels of SDF-1 in the BM are required for HSPC homeostatic maintenance, acting via CXCR4 to ensure cell quiescence and retention. Perturbation of the fundamental balanced SDF-1/CXCR4 signaling axis in the BM during mobilization is associated with a transient increase of SDF-1 levels because of its secretion by BM stromal cells followed by its release to the circulation. Local expression of SDF-1 in the BM is further reduced in response to active proteolytic cleavage by many enzymes that are activated by the secreted SDF-1, and BM HSPC gain increased CXCR4 expression and thereafter are guided into the periphery.[79,81,97] G-CSF–induced mobilization of murine HSPCs from their BM niches inhibits SDF-1 transcription and production by BM

stromal cells, including osteoblasts[97] and reticular Nestin-positive MSCs.[11] Dynamic perturbation in the guiding signal SDF-1 in the surrounding BM niche supporting cells is also accompanied by increased CXCR4 expression on the surface of immature human BM $CD34^+$ cells[79,98] and primitive $CD34^+CD38^-$ cells.[79] This direct HSPC regulation as well as indirect inhibitory effect of BM stromal cell function demonstrates the importance of interactions between SDF-1 and CXCR4 in retaining HSPCs; disruption of this fine-tuned axis leads to HSPC mobilization.

Rapid HSPC mobilization is a fast process that does not involve proliferation, typically peaking within minutes to hours after administration. One such agent is the rapid mobilizer AMD3100 (also known as Plerixafor and Mozobil), which was first characterized as a CXCR4 antagonist according to its ability to inhibit migration toward SDF-1 in vitro[99,100] because it reversibly blocks SDF-1 binding to CXCR4. Upon its administration in vivo, AMD3100 disrupts the SDF-1–CXCR4 axis, thus facilitating both human $CD34^+$ and murine HSPC mobilization in the time frame of a few hours.[101] AMD3100 is approved for clinical HSPC mobilization protocols in combination with G-CSF in patients with non-Hodgkin lymphoma and multiple myeloma undergoing autologous transplantation.[102] Prolonged G-CSF-induced HSPC mobilization shares some similarities with rapid mobilization protocols but also reveals mechanistic differences. AMD3100 and G-CSF act in synergy to facilitate enhanced HSPC egress from the BM.[103] In addition to the kinetic differences, the gene expression profile signatures of immature human $CD34^+$ cells following G-CSF, AMD3100 or the combined treatment is largely different, demonstrating unique mechanisms of activity driving these two powerful mobilizers.[104] Disrupting the SDF-1–CXCR4 axis by the antagonistic effect of AMD3100 cannot fully explain the mechanism leading to rapid HSPC mobilization because neutralizing antibodies against CXCR4, which also inhibit SDF-1–induced migration in vitro, are incapable of inducing in vivo HSPC mobilization.[79,81,105] Current understanding suggests that HSPC mobilization by AMD3100 is an active process, consistent with the notion that stem cell detachment from their nursing microenvironment and recruitment to the circulation is a highly regulated process. Recent findings suggest that AMD3100 has also an agonistic effect by mediating rapid SDF-1 secretion from murine BM $CXCR4^+$ stromal cells followed by its rapid release to the circulation.[81] Mobilized human $CD34^+$ progenitor cells following AMD3100 and G-CSF treatment have increased SDF-1 chemotaxis in vitro,[101] suggesting that AMD3100 inhibition in vivo is transient and short lived. SDF-1 secretion from BM stromal cells could induce the removal of AMD3100 from $CXCR4^+$ HSPCs, allowing their enhanced SDF-1–mediated migration and rapid mobilization in vivo. These dynamic fluctuations, enabling transient and local SDF-1 gradients toward the blood, emerge as an essential mechanism for egress and rapid mobilization of immature progenitor cells and are less important for mature leukocytes egress.[81] SDF-1 secretion by human and murine BM stromal cells, driven by either pharmacologic manipulation or homeostatic condition, is a cell-contact–dependent event mediated by connexin 43/45 gap junctions.[56] Enhanced SDF-1 release from BM stromal cells and its translocation to the circulation, together with the short transient inhibitory effect of AMD3100, actively promotes HSPC recruitment from the BM in the course of rapid mobilization. Of note, murine $Sca\text{-}1^+/c\text{-}Kit^+/Lin^-$ progenitor cells recruitment to sites of injury is also associated with rapid SDF-1 secretion from thrombin-activated platelets, thereby supporting host defense and repair mechanisms.[106] Thrombin and its receptor protease-activated receptor-1 (PAR-1) play an important role in coagulation after injury and bleeding. Interestingly, thrombin stimulation results in rapid SDF-1 secretion from murine BM stromal cells, including from rare Nestin-positive MSCs, which functionally express PAR-1.[107] Accordingly, PAR-1 activation in vivo induces rapid murine HSPC mobilization within 1 hour via CXCR4 upregulation and a dramatic decrease of SDF-1 in the BM.[107] Indeed, PAR-1 was found to be significantly increased on mobilized human $CD34^+$, suggesting the involvement of PAR-1 signaling in human HSPC trafficking to the circulation as part of G-CSF mobilization.[108]

Collectively, the SDF-1–CXCR4 axis plays a pivotal role in directing steady-state egress and enhanced recruitment of HSPCs. Altering SDF-1 levels in the BM and the blood thereby dynamically affects circulating HSPC numbers and may be exploited for future clinical protocols.

Stem Cell Trafficking is Coordinated by the Brain–Bone–Blood Triad

The sympathetic nervous system (SNS) interacts with the immune system and exerts direct and indirect influences on stem and progenitor cells function. Human and murine BM are highly innervated.[109-111] The mammalian nervous system regulates the immune system in many acute physiologic conditions, especially during mental stress, as part of the "fight-or-flight" response of the adrenergic SNS.[112] Acute and chronic psychologic stresses, mediated by neuronal signals, can affect HSPC function and recruitment to the periphery as a front line of defense.[88,113] Neuronal receptors are dynamically expressed on primitive human $CD34^+/CD38^-$ HSPCs, with a gradual decrease as the cells progressively differentiate. G-CSF–mobilized human $CD34^+$ show higher catecholaminergic receptor expression compared with nonstimulated human cord blood or BM-derived $CD34^+$ progenitor cells,[114] suggesting a role for the SNS in regulating HSPC recruitment and clinical mobilization. The involvement of the SNS in the regulation of HSPC trafficking was further supported by murine models showing that mice lacking norepinephrine synthesis and mice that were subjected to pharmacologic catecholaminergic ablation exhibited inability to induce mobilization in response to G-CSF.[115] Neurotransmitters that have a chemotactic activity for both resting and G-CSF–stimulated human $CD34^+$ HSPCs induce HSPC motility and BM repopulation of immune deficient NOD/SCID mice via activation of the canonical Wnt signaling pathway.[114] Human HSPC mobilization is also regulated in a paracrine fashion by the endocannabinoid system, representing a pivotal neuroprotective mechanism whereby BM stromal cells express endocannabinoids and HSPCs express the cannabinoid receptor CB2. Indeed, cannabinoid receptor activation reduced CXCR4 expression, rapidly mobilized murine HSPCs, and enhanced mobilization by G-CSF.[116]

Bone marrow SDF-1 levels oscillate in a circadian manner, a process orchestrated by rhythmic β_3 adrenergic signals delivered by the nervous system,[117] verifying the notion that HSPC egress from the murine BM is not a random event but is rather triggered and synchronized by functional BM SDF-1 expression. Accordingly, expression of CXCR4 by murine BM HSPCs also demonstrates circadian oscillations.[118] Enforced mobilization by G-CSF or AMD3100 is also controlled by the molecular clock, such that synchronized CXCR4 and SDF-1 levels can influence the yield of collected HSPCs.[118] Studies in humans have revealed circadian fluctuations of human $CD34^+/CD38^-$ stem cells in peripheral blood, suggesting the importance of circadian rhythms in pharmacologic mobilization protocols to increase the success of HSPC transplantation.[118] Circadian rhythms of HSPC egress during low SDF-1 levels in the BM are coupled to environmental dark–light cycles, demonstrating how signals initiated in the eyes and brain can synchronize bone remodeling and HSCs egress via the SNS.[119] The molecular clock in the nervous system is only one arm by which it controls HSPC egress. The essential course of SDF-1 secretion from BM stromal cells to the circulation, in order to induce HSPC mobilization, was also found to be regulated by neurotransmitter signaling. Catecholaminergic stimulation with norepinephrine induces rapid SDF-1 release to the periphery from BM stromal cells expressing the β_2-adrenergic receptor, thus enabling murine HSPC mobilization within 1 hour.[81] The SNS also affects murine HSPC steady-state egress and promotes G-CSF–induced mobilization indirectly by suppression of endosteal osteoblasts function, hence resulting in down-regulation of SDF-1 expression in the BM.[97,115]

Adrenergic stimulation reduces bone formation via leptin dependent neuronal regulation, indicating that bone formation and osteoblast function are regulated by the SNS as well.[120] Accordingly, repetitive

G-CSF treatments in mice inhibit the transcription of genes that regulate HSPC maintenance and retention in the BM in the supportive Nestin-positive niche cells, such as SDF-1 and Kit ligand.[11] By contrast, in vivo PTH administration primes Nestin-positive MSCs to differentiate more rapidly into osteoblasts[11] and doubles the HSPC pool.[51] PTH stimulates osteoblasts to produce the cytokines receptor activator of nuclear factor κ-B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF), therefore facilitating marrow monocyte differentiation into mature osteoclasts that initiate remodeling by enhanced bone resorption.[121] The bone is a highly dynamic tissue through the process of bone remodeling. Changes within the BM microenvironment after administration of RANKL, the osteoclast differentiation cytokine, were associated with preferential mobilization of immature murine progenitors.[90] Bone resorption by HSC-originated osteoclasts and bone formation by osteoblasts, originated from mesenchymal progenitors, are two coupled processes whereby bone resorption is normally followed by new bone formation.[122] This balanced process is tightly regulated by complex signals of hormones, cytokines, chemokines, and inflammatory factors.[123] Inhibition of osteoblast function by the powerful mobilizing agent G-CSF dictates osteoclasts recruitment and increased activity. It should be noted, however, that after G-CSF administration, osteoblasts first proliferate before their suppression, thus enabling HSPC expansion before the subsequent mobilization.[124] The endosteal stem cell niche is dynamic, producing hematopoietic cells on demand, and is dramatically accelerated in response to alarm signals because of injury.[123] Concomitantly, bone-degrading osteoclasts are directly involved in mobilization of progenitor cells from the BM to the circulation, both in homeostatic and stress conditions.[90] Robust activation of bone resorbing tartrate-resistant acid phosphatase (TRAP)-positive active osteoclasts along the bone-interface endosteum regions in various physiologic stress conditions, such as bleeding and bacterial infection, induces preferential HSPC mobilization.[123] The involvement of osteoclast activation in mediating HSPC egress and mobilization is also evident in CD45-deficient mice, possessing defective osteoclast activity and altered metaphysial trabecules, which exhibit impaired HSPC release to the circulation during G-CSF mobilization.[125] One of the driving forces behind HSPC mobilization after osteoclast activation may be an alteration in intercellular communication among the stromal supporting cells in the BM microenvironment. SDF-1 secretion is cell contact dependent mediated via connexin 43/45 gap junctions,[56] suggesting that osteoclast activation transiently breaks the tight BM stromal cell syncytium, which results in SDF-1 downregulation, reduced retention, and HSPC mobilization.

Myeloid BM macrophages are emerging as additional key participants in the systemic response to G-CSF stimulation. The endosteal-specific murine macrophages, osteomacs, which support bone-forming osteoblast function, are dramatically depleted after repetitive G-CSF stimulations followed by suppression of osteoblasts and their adhesion interactions with HSPCs, leading to HSPC release into the blood.[126,127] Depletion of another BM-derived macrophage subpopulation, defined as $CD169^+$ macrophages, known to support the function of Nestin-positive MSC, induced marked HSPC egress and mobilization.[127] BM macrophages might also serve as a connecting link between signals of the SNS and osteoblast suppression.[80,128] Taken together, complex hierarchical differentiation of monocytic precursors, including $CD169^+$ macrophages, osteomas, and bone-degrading osteoclasts, dictate HSPCs' fate via a wide variety of signals.

Proteolytic Enzymes and Hematopoietic Stem and Progenitor Cell Mobilization

The BM microenvironment is highly vascularized, containing large blood vessels and sinusoids. This endothelial gatekeeper function is essential to preserve HSPCs confined to the BM. Mobilization upon clinical G-CSF administration or chemotherapy is associated with disrupted endothelial integrity and increased permeability of BM sinusoids, the site at which active transition of HSPCs from the BM to the circulation takes place.[9,129] Bordering endothelial gaps, as part of the complex mechanism to enhance HSPC mobilization, are believed to be under the regulation of proteolytic enzymes including MMP-9. This enzyme is highly produced in the BM after G-CSF treatment[130] and is capable of degrading components that comprise the endothelial tight junctions and are responsible for endothelial integrity.[131] Functional osteoclasts secrete several proteolytic enzymes, including MMP-9 and the major bone-resorbing enzyme cathepsin K during homeostasis, and more intensively under stressed conditions, such as after G-CSF administration. These events are followed by proteolytic deactivation of factors providing stem cell retention signals in the endosteum region such as SDF-1, osteopontin, and SCF, eventually leading to HSPC mobilization.[90,123] Release of membrane-bound SCF, an important lodgment factor for murine stem cells[132] from the BM to the peripheral blood because of SDF-1–induced proteolytic activity of MMP-9 further demonstrates the involvement of MMP-9 in the mobilization process.[130] The transient increase of SDF-1 levels in the marrow cavity followed by its rapid secretion to the circulation during AMD3100 administration[81] or secretion and degradation after repetitive G-CSF stimulation,[79] emerges as a pivotal event in the mechanism of HSPC mobilization. In response to the G-CSF regimen, the adult BM becomes a highly proteolytic microenvironment caused by neutrophil proliferation and activation, resulting in the release of large amounts of neutrophil proteases such as neutrophil elastase, cathepsin G, and MMP-9 directly into the BM cavity.[133] The chemotactic potential of SDF-1 is reduced after cleavage of its N-terminal domain as a consequence of proteolytic activity by several degrading enzymes, including CD26/dipeptidylpeptidase IV,[134] neutrophil proteases,[135] and cathepsin K.[90] Secretion of functional MMP-9 is also associated with AMD3100 administration, suggesting the involvement of the proteolytic enzyme MMP-9 in rapid HSPC mobilization.[136,137] Another important enzyme, the cell surface protease membrane type 1 MMP (MT1-MMP), which is expressed by immature human $CD34^+$ cells and by mature myeloid cells, can inactivate SDF-1 and CD44 by proteolytic cleavage.[138] Upon G-CSF treatment, MT1-MMP expression is increased on human $CD34^+$ progenitor cells followed by downregulation of its endogenous inhibitor RECK and CD44, facilitating loss of progenitor cell retention and allowing their egress and mobilization.[139] Importantly, MT1-MMP expression positively correlates with egress and G-CSF mobilization of human $CD34^+$ progenitors[139]; thus, MT1-MMP may predict clinical mobilization outcome. The thrombolytic agent plasminogen, which is activated by tissue-type and urokinase-type plasminogen activator (tPA and uPA) to plasmin, was found to be a critical regulator of murine HPSC mobilization,[81,140-142] mediating MMP-9 secretion in a CXCR4-dependent manner.[98] Current understanding strongly suggests that proteases and MMPs are part of the major stem cell migration and mobilization regulatory machinery, inactivating BM-derived growth factors and chemokines, which are responsible for immature and maturing leukocyte adhesion and retention, thus facilitating enhanced movement across the physical barrier of the marrow extracellular matrix in response to AMD3100 or G-CSF stimulations.

Additional Control of Hematopoietic Stem and Progenitor Cell Mobilization

One of the major pathways by which HSPCs directly and indirectly gain motility is the generation of reactive oxygen species (ROS). Repetitive G-CSF–induced mobilization involves ROS generation directly in primitive hematopoietic progenitors, correlating with their enhanced egress and motility, involving hepatocyte growth factor (HGF) and its cognate receptor c-Met signaling.[105] Concomitantly, inhibition of ROS by the antioxidant NAC (*N*-acetyl cysteine) led to a preferential inhibition of AMD3100-induced and G-CSF–induced murine HSPC mobilization.[81,105] HSPC recruitment to the peripheral blood is also regulated by the chemoattractant lipid S1P as part of steady state egress as well as stress-induced mobilization.[143,144] In humans, S1P induces chemotaxis of immature $CD34^+$ cells that express the S1P receptor sphingosine-1-phosphate receptor-1

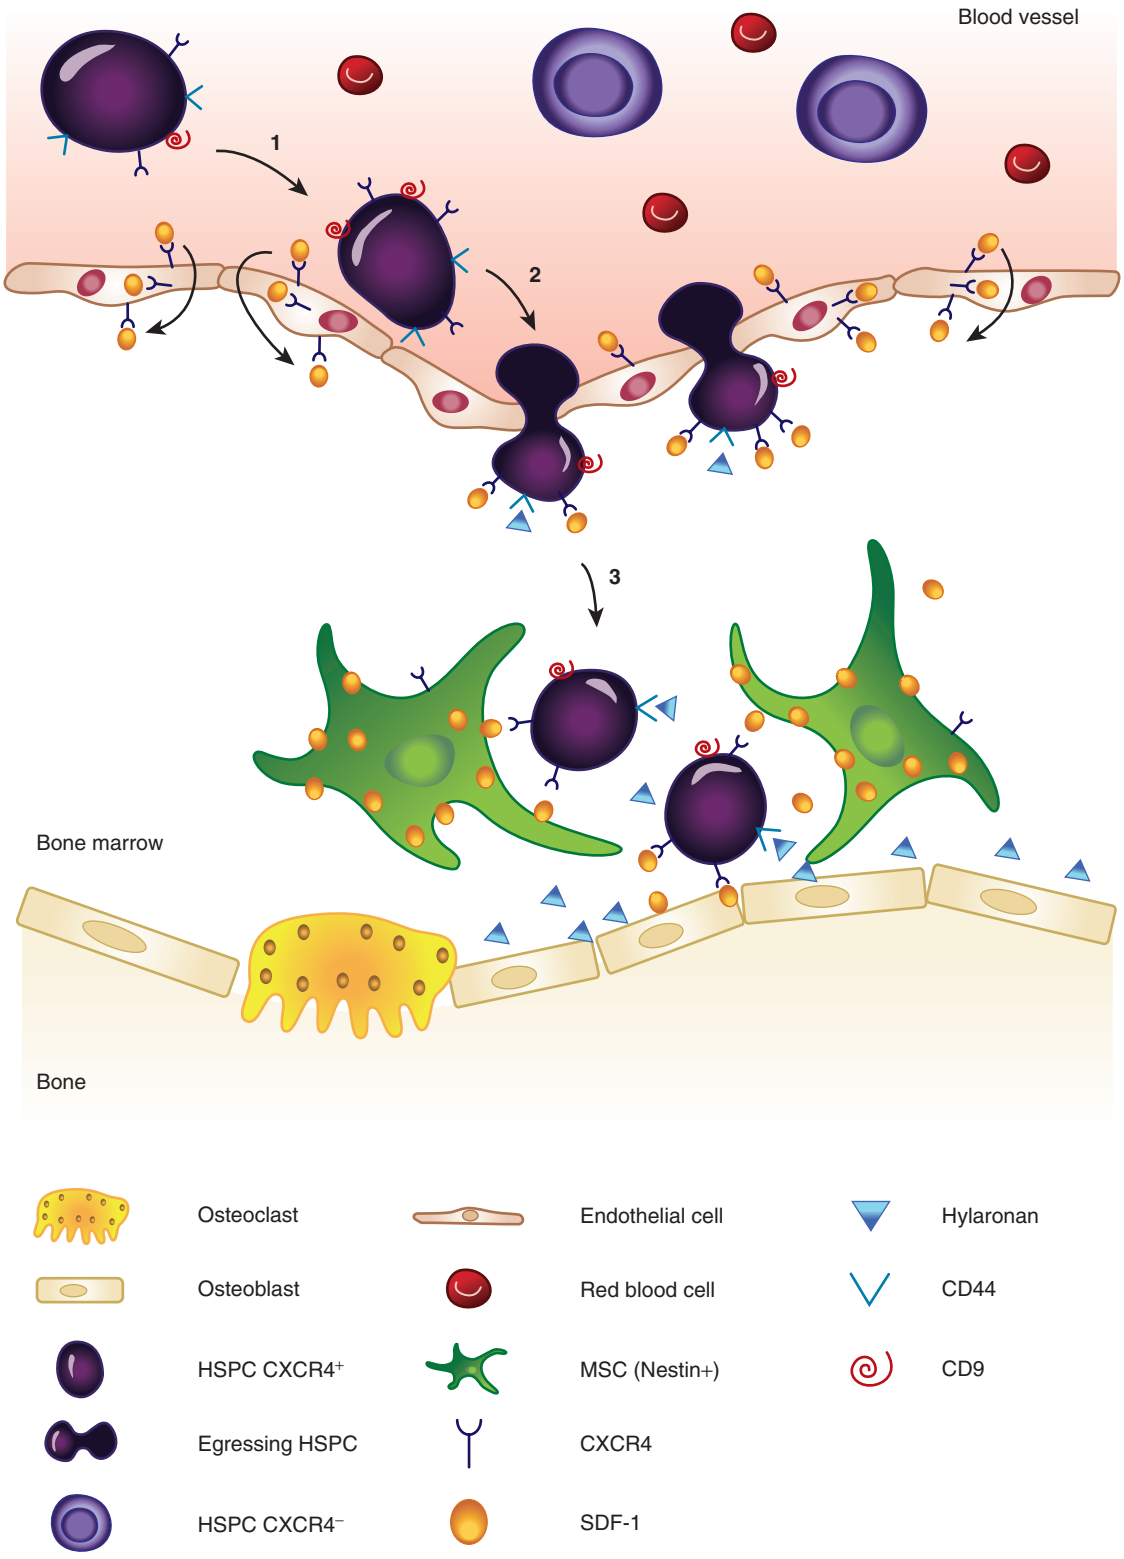

Figure 12-1 HOMING OF TRANSPLANTED HEMATOPOIETIC STEM AND PROGENITOR CELLS (HSPCs) TO THE BONE MARROW (BM). Rolling and firm adhesion *(1)* of navigating HSPC from the blood circulation via the BM sinusoid after their transplantation is followed by transendothelial migration across the physical blood–BM barrier *(2)*. Stromal cell–derived factor-1 (SDF-1)–CXCR4 interaction, including translocation of SDF-1 to the abdominal side of the endothelium and its sequential secretion to the BM, as well as CD44–hyaluronan interaction and CD9, are key regulators of human stem cell homing to BM stromal supportive niches *(3)*.

($S1P_1$).[145,146] Accordingly, murine HSPC egress from extramedullary tissues depends on S1P receptor upregulation and migration toward higher S1P concentrations in the lymph and blood circulations.[147] During G-CSF–induced mobilization, S1P concentration is augmented in the peripheral blood[143,144] and concomitantly decreases in BM fluids,[143] suggesting a potential chemotaxis induced mobilization mechanism via the formation of a S1P gradient toward the blood.[143,144] The S1P–$S1P_1$ axis is also an important regulator of rapid mobilization by AMD3100 because inhibition of this axis reduced the level of progenitor cell recruitment to the blood in mice.[144]

Altogether, immunosurveillance by hematopoietic progenitor cell trafficking, as part of the host defense and repair mechanism, is enabled via a dynamic complex interplay of mediators, governed by SDF-1–CXCR4 signaling, proteolytic enzymes, bone remodeling, and signals from the nervous system, regulating HSPC egress and mobilization under stress conditions.

FUTURE DIRECTIONS

*"In order to keep your **balance,** you must keep **moving.**"*
—Albert Einstein

*"I find the great thing in this world is not so much where we stand, as in **what direction we are moving.**"*
—Oliver Wendell Holmes

This chapter discusses mechanisms and pathways involved in the regulation of HSPC homing and retention, as well as HSC egress, recruitment, and mobilization, emphasizing the major role that the SDF-1–CXCR4 axis plays in the regulation of these complex processes. The brain–bone–blood triad dynamically regulates both HSCs and BM stromal stem cells via bone turnover, circadian rhythms, and stress signals, producing leukocytes on demand as part of host defense and repair mechanism. Successful BM reconstitution requires directed stem cell movement from the circulation, across the blood–marrow barrier into their specialized niches in the BM wherein stem cells proliferate and differentiate to give rise to multilineage hematopoietic cells, while maintaining a small pool of primitive stem cells (Fig. 12-1). Most HSPCs reside in the BM, anchored to the endosteal region and perivascular sites. However, a rare population of circulating progenitors continuously egresses to the blood as part of homeostasis. Although these low circulating levels are dramatically increased together with maturing leukocytes as part of host defense and repair mechanisms, it is yet unknown what is the biologic advantage of an active directional migration of immature stem cells from the safe shore of the BM cavity to the turbulent blood circulation during homeostasis. Clinical protocols such as repeated G-CSF and rapid AMD3100 stimulation induce massive recruitment of stem and progenitor cells to the circulation (Fig. 12-2). This process is used clinically to harvest HSPCs for transplantation.

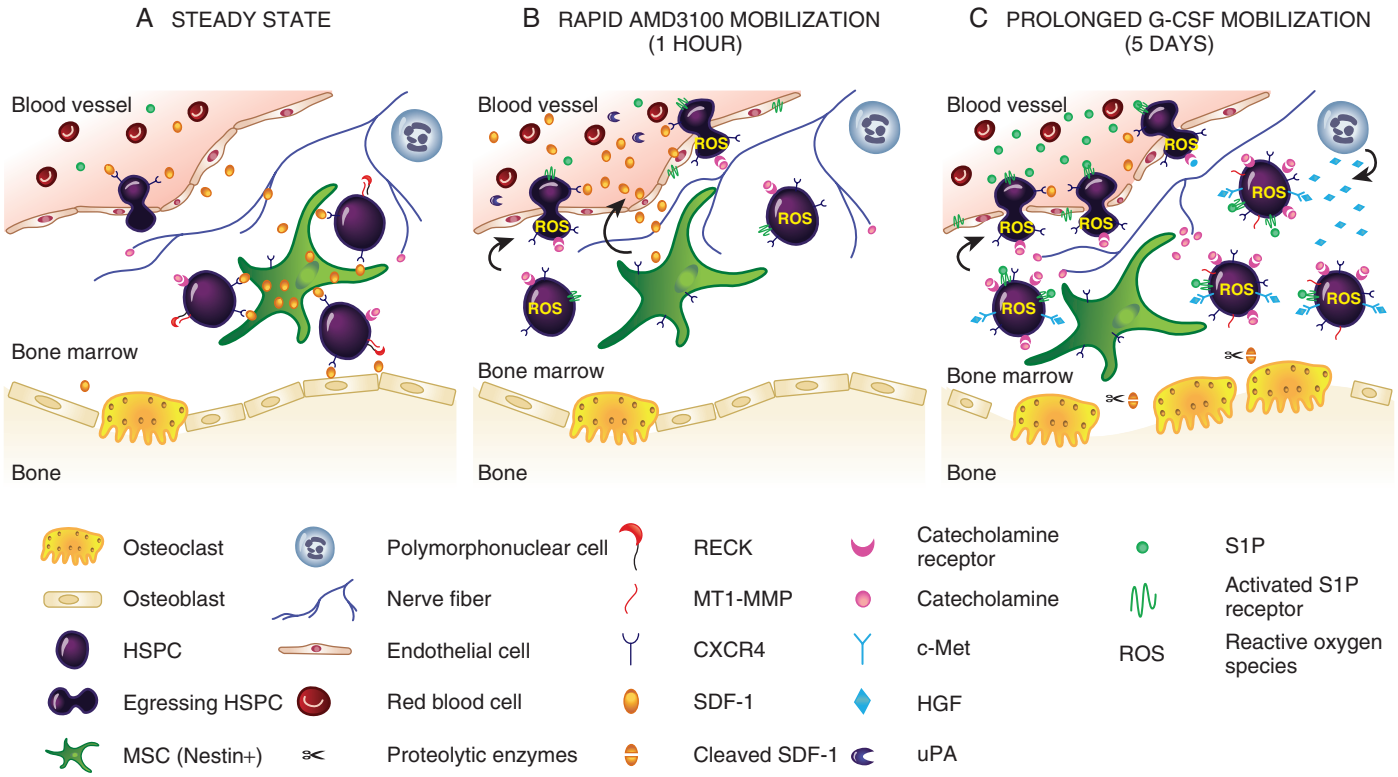

Figure 12-2 HEMATOPOIETIC STEM AND PROGENITOR CELL (HSPC) EGRESS AND MOBILIZATION. **A,** During steady state, HSPCs are localized and anchored in special stromal niches, closely associated with bone marrow (BM)–supporting cells, including osteoblasts and Nestin-positive mesenchymal stem cells (MSCs) that prevent their uncontrolled differentiation. The quiescent state of HSPCs is maintained via signaling of the stromal–cell derived factor-1 (SDF-1)–CXCR4 axis and inhibition of membrane type 1 metalloprotease (MT1-MMP) by RECK. **B,** Rapid HSPC mobilization after AMD3100 stimulation temporarily disrupts SDF-1–CXCR4 interactions and induces rapid SDF-1 secretion from BM $CXCR4^+$ stromal cells, including SDF-1–enriched Nestin-positive MSCs, resulting in local increase in SDF-1 levels in the BM followed by its release to the circulation. Secretion and rapid release of SDF-1 to the circulation enhance urokinase-type plasminogen activator (uPA) activation and increase expression of sphingosine-1-phosphate (S1P) receptors on HSPCs' surfaces. Consequently, an increase in intracellular reactive oxygen species (ROS) levels mediates HSPC recruitment and rapid mobilization within 1 hour. **C,** Repetitive granulocyte colony-stimulating factor (G-CSF) stimulation induces HSPC mobilization via osteoclast activation, alternation of sympathetic nervous system (SNS) signaling, and attenuation of osteoblast and MSC function followed by reduction of SDF-1 in the BM, CXCR4 upregulation, and proteolytic enzyme activation (including upregulation of surface MT1-MMP), leading to HSPC proliferation, differentiation, and increased mobilization to the circulation. During G-CSF–induced mobilization, S1P levels in the circulation are increased, thus intensifying the gradient between the blood and the BM. Increased production of hepatocyte growth factor (HGF) from polymorphonuclear cells in the BM results in HGF–c-Met axis activation, which in turn augment intracellular ROS generation and facilitating HSPC mobilization.

Relevance to Clinical Hematology

Optimal HSC migration from the BM to the circulation (mobilization) for donor cell transplant harvest and from the recipient blood into the BM (homing) for stem cell lodgment is an essential prerequisite for successful BM reconstitution in clinical transplantation. Discussed in this chapter, experimental systems involving human and murine HSPCs enable dissecting these migration processes to identify regulatory mechanisms to improve clinical settings. Current understanding of HSPC biology reveals that these cells home to the BM homeland, where they proliferate and differentiate, giving rise to multilineage hematopoietic cells while maintaining a small pool of primitive stem cells. The majority of HSPCs remain confined to the BM cavity in a nonmotile mode, adjacent to niche supportive cells that preserve them in a quiescent, nonproliferative mode, but a very low level of primitive progenitors and stem cells also continuously egress to the circulation as part of homeostasis. The levels of these rare migrating HSPCs are dramatically enhanced during alarm situations caused by injury and inflammation as part of host defense and repair mechanism. The physiologic process of enhanced HSPC recruitment from the BM has been used clinically to accelerate stem and progenitor cell migration to the circulation. Thus, collection of HSPCs from the donor's peripheral blood, rather than from their BM became the most common clinical protocol for BM transplantation (BMT).

Clinical BMT has gained immense success within the past 4 decades in the treatment of malignant hematologic diseases and immunodeficiency states by providing long-term immune recovery after high-dose chemotherapy.[152] The basic premise in BMT is using either a patient's own stem cells (i.e., autologous BMT) used primarily as stem cell support for myeloma or lymphoma undergoing intensive chemotherapy. Alternatively, allogeneic BMT, performed for the most part in the setting of marrow-infiltrating malignancies such as leukemia, uses donor stem cells infused to a patient, thus capitalizing on the graft-versus-leukemia effect, which affords significant reduction in relapse rate. One of the major clinical obstacles facing BM transplant experts today is the mobilization of the so-called "difficult mobilizers" who fail to mobilize the required amount of CD34 progenitors.[153] Known risk factors for insufficient number of HSPCs after mobilization include older age, previous failed mobilization, heavy BM infiltration by tumor cells, and previous chemotherapy and radiotherapy, to name just a few. Several strategies have tried to address this clinical problem using optimize current mobilization protocols, among them high-dose G-CSF regimens, erythropoietin, SCF, and chemomobilization achieved by chemotherapy treatment combined with G-CSF. Despite the wide gamut of therapeutic strategies used, most of them have either failed to show a clear advantage to standard mobilization regimens or were associated with substantial adverse effects (chemomobilization). With the recent introduction of the CXCR4 antagonist AMD3100 (also termed Mozobil and Plorexifor), there is renewed optimism in the management of difficult to mobilize patients. AMD3100 mediates rapid secretion of SDF-1 from BM stromal cells and its release to the circulation,[81] resulting in $CD34^+$ progenitor mobilization.[101] Treatment with AMD3100 exhibits marked synergism with G-CSF, suggesting their different and complementary mechanisms of action to induce HSPC mobilization. Several studies have shown its success in mobilization of previously failed myeloma in non-Hodgkin lymphoma and Hodgkin lymphoma patients.[154]

Clearly, because BMT is used increasingly in elderly adults and patients previously exposed to intense chemotherapy, novel approaches for optimizing mobilization are warranted. Several promising approaches are looming over the clinical horizon, among them are novel mobilization agents such as AMD3465,[155] SB-251353,[156] T140,[157] and PTH[158] acting in its capacity as a pivotal regulator of the hematopoietic niches. Additional avenues to be explored in this area include the use of cord blood, which at present is limited to pediatric patients and adults of low body weight because of the low number of $CD34^+$ progenitors contained in each cord blood unit. For this reason, the major disadvantage of cord blood transplantation in adult patients is delayed engraftment. Approaches aimed at overcoming the delayed engraftment with cord blood transplantation include double cord blood transplants or together with mobilized or BM-derived $CD34^+$ cell infusion from a matched donor to achieve transient engraftment until the cord blood cells reconstitute the BM.[159] In addition, circumventing this inherent limitation of cord blood use may be achieved by improving HSPCs' homing potential. For instance, inhibition of CD26 allows augmented engraftment of stem cells to the recipient's BM.[38] Upregulation of CXCR4 by PGE_2 stimulation increases SDF-1 chemoattraction to the BM.[28] Another pathway is activated by CD44 glycozilation,[45] which may enhance navigation of treated MSC to the BM. Taking into consideration the bone and BM niches integrity, influencing factors such as age, timing of mobilization, and interplay among different mobilizing agents might be crucial in optimizing HSPCs yield after mobilization and their homing after transplantation. This approach might lead to advanced development of new safe and efficient therapeutic strategies for HSC transplantation protocols.

Various signals provided during homeostasis and stress-inducing conditions by the BM tissue and by peripheral organs determine the fate and localization of HSCs. Of note, because malignant stem cells mostly originate from normal HSPCs, they also functionally express the CXCR4 receptor.[148,149] The BM niches provide protection for hematologic malignant cells, including malignant stem cells from chemotherapy, conferred by interactions with stromal cells, mainly via the SDF-1–CXCR4 signal axis. The motile nature of HSPCs also holds true for hematologic malignant cells. Priming of patients with mobilizing agents, such as G-CSF and AMD3100, might break the protective machinery provided by BM stromal cells, induce cell chemosensitization, and subsequently will provide eradication of the malignant disease.[150,151]

CHAPTER 13

VASCULAR GROWTH IN HEALTH AND DISEASE

Janusz Rak

HEMOSTATIC, HEMATOPOIETIC, AND VASCULAR SYSTEMS AS A FUNCTIONAL CONTINUUM

Although specific demands of practice, concepts, and methodologies may have defined the unique scope of current hematology, the underlying biologic processes do not occur in isolation. Thus it is increasingly obvious that diseases affecting bone marrow and peripheral blood are closely intertwined with the state of the vascular system,[1] which acts as a niche, conduit, and regulator of many of these events.[2] This is exemplified by the anatomic proximity and interactions among several related cellular populations, including hematopoietic progenitors, their derivatives, endothelial cells and their precursors, platelets, and other components involved in blood vessel formation, repair, homeostasis, and patency.[2,3] The remarkable recent progress in understanding the molecular mechanisms involved in communication between these cells increasingly informs medical considerations and drug discovery efforts.[2,4,5] For instance, agents that block vascular growth (antiangiogenics), which are currently used to treat solid tumors, elicit hematologic perturbations[6] and are being considered for treatment of hematopoietic malignancies.[7] Indeed, hematopoietic, hemostatic, and vascular compartments can be viewed as a functional continuum, both in health and in disease.

CONSTITUENTS OF THE VASCULAR SYSTEM

The hematopoietic and vascular systems emerge from a common progenitor cell (hemangioblast) early during embryogenesis. Subsequently the vascular lineage evolves to form a network of channels that integrate, control, and reflect the structure and function of the tissues (parenchyma) and organs that they supply.[8] Local characteristics of the vascular system are superimposed on a more general, hierarchical branching pattern (arborization) and arteriovenous directionality of the circulation. Structurally, distinct lymphatics emerge from the venous system to return extravascular (interstitial) fluid and extravasated cells to the venous circulation.[2]

Blood vessels are not only the essential supply routes of nutrients and oxygen to tissues (parenchyma), but also conduits of long-range regulatory signals (hormonal/endocrine) and an important source of paracrine cues that act on surrounding cells in a perfusion-independent (angiocrine) manner.[2,9] Postnatal tissue maturation imposes a quiescent phenotype throughout the vascular system, a state that is interrupted by only a small number of transient growth events, such as posttraumatic tissue regeneration, wound healing, vascular repair, or cyclic changes in reproductive organs. This quiescent state may be chronically compromised in certain pathologic conditions (inflammation, hyperplasia, or cancer), which can lead to unscheduled or abnormal vascular growth.[2] Out of several forms of such growth, vasculogenesis and angiogenesis stand out as fundamentally important and distinct. In vasculogenesis, endothelial progenitor cell self-assembly results in the formation of new vascular channels (e.g., during embryogenesis). In contrast, angiogenesis is a process whereby preexisting vascular channels are extended to form additional capillary loops (e.g., during tissue remodeling and in cancer).[2]

Cells Involved in Vascular Growth

Specialized endothelial cells (ECs) constitute the crucial structural and functional element of the adult vasculature. ECs create antithrombotic luminal surfaces within all blood vessels, produce an active interface between the blood and the surrounding tissues, control the flux of fluids and macromolecules (permeability), and are the key component of vascular growth processes. Such growth not only involves cessation of the quiescent state in subsets of resident ECs, but is also associated with multiple systemic events, such as emission of cytokines into the circulation and mobilization of cells from the bone marrow, including putative endothelial progenitor cells (EPCs), hematopoietic stem cells, and myeloid cells (bone marrow–derived cells [BMDCs]).[10] These cells serve as surveillance and regulatory mechanisms that control and coordinate the responses of the peripheral vasculature (Fig. 13-1).[11,12] In established blood vessels the functionality of the endothelial tube is dependent on the support of abluminal basement membrane (BM), which is shared between these cells and one or more layers of contractile mesenchymal cells of the blood vessel wall (mural cells). Sparse networks of these cells (here called pericytes) are associated with capillary endothelium, whereas continuous sheets of mural smooth muscle cells cover the precapillary/postcapillary vascular segments (arterial and venous, respectively).[2] The thickness and complexity of the vessel wall differs between veins and arteries and increase with vascular hierarchy. So much so, that the multilayered walls of large arteries contain their own capillary networks *(vasa vasorum),* the growth of which can contribute to the formation of atherosclerotic plaques.[13] Blood vessel integrity and growth are also dependent on platelets and the hemostatic system (tissue factor, thrombin, thrombin receptor/protease-activated receptor 1 [PAR1]), other PARs the fibrinolytic system, and other effectors), all of which play important parts in the regulation of vascular continuity, patency, and permeability.[2] Coagulation proteases not only regulate clot formation upon injury but also elicit signals within the surrounding vascular, inflammatory, and parenchymal cells, thereby modulating these processes.[9]

Molecular Regulators of Vascular Responses

The state of the vascular networks is controlled by a web of intercellular communications, which are executed by soluble growth factors, adhesion molecules, extracellular matrix (ECM) molecules, cell-cell contacts, the hemostatic system, various proteases, and the intercellular exchange of molecules (proteins, messenger ribonucleic acid [mRNA] and micro-RNA [miRNA]) by membrane microvesicles.[12] This array of mediators includes those essential for vascular homeostasis and ones that are more pleiotropic in nature, serving to stimulate or inhibit vascular growth (Table 13-1).[1,2]

Vascular Endothelial Growth Factors

Vascular endothelial growth factor-A (VEGF-A), is also known as VEGF or vascular permeability factor.[3] VEGF is the key member of a larger family of related polypeptides, which includes VEGF-B,

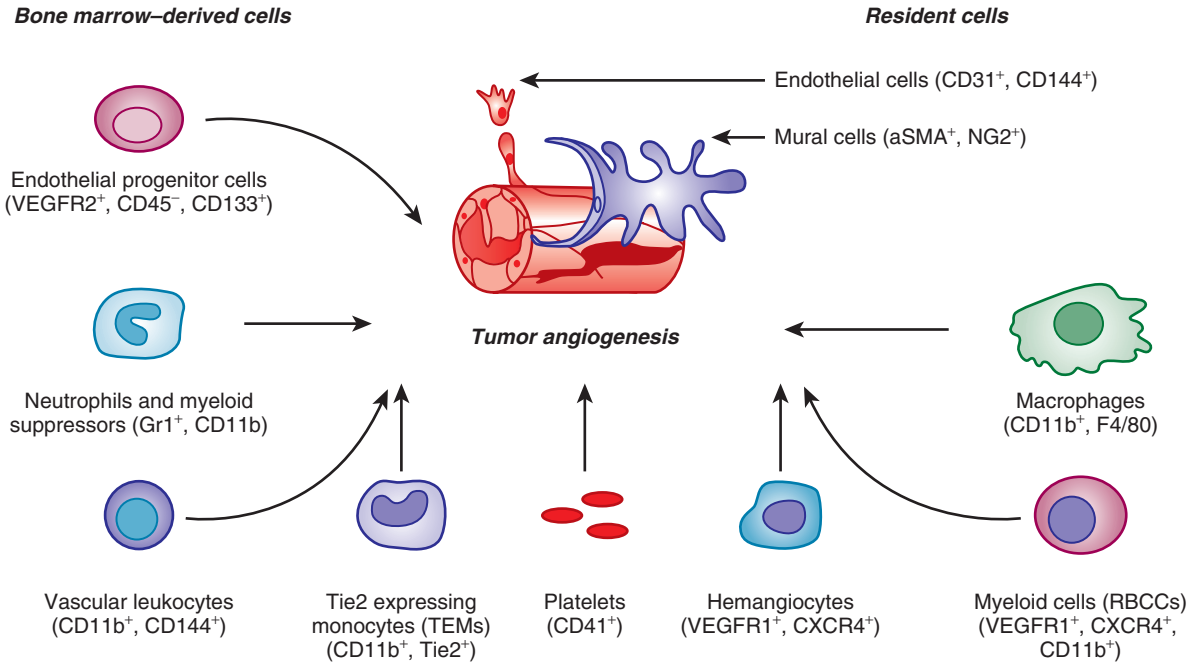

Figure 13-1 CELL POPULATIONS INVOLVED IN TUMOR ANGIOGENESIS. Cells involved in blood vessel formation include endothelial cells, their progenitor cells, mural cells (pericytes), and several population of bone marrow–derived cells, as well as angiogenic fibroblasts, cancer cells, and immune effectors not included in this diagram. *VEGFR,* Vascular endothelial growth factor receptor. *(Modified from Kerbel RS: Tumor angiogenesis.* N Engl J Med *358:2039, 2008.)*

VEGF-C, VEGF-D, VEGF-E, VEGFR-F, and placenta growth factor (PlGF).[5] Upon dimerization these factors bind to their tyrosine kinase receptors (RTKs/VEGFRs), including VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3/Flt-4, often acting in conjunction with their neuropilin coreceptors (NRP1, NRP2).[2] The specificity of these interactions is relatively restricted, as indicated in Fig. 13-2. For instance, VEGF-A interacts with VEGFR2, VEGFR1, and VEGFR3, whereas PlGF is selective for VEGFR1. The distribution of different VEGFRs on vascular (VEC) and lymphatic (LEC) endothelial cell subsets, as well as among EPCs, hematopoietic, myeloid, and certain tumor cells defines the known biologic activities of various VEGF ligands. The effects of VEGF include stimulation of VEC mitogenesis, migration, survival, morphogenesis, and vascular permeability (e.g., through formation of intercellular gaps or transcellular structures know as *fenestrae*). The signaling activity of VEGFR2 is crucial for these processes, whereas VEGFR1 is often expressed as a soluble splice variant (sFlt-1) that neutralizes VEGF (acts as VEGF "sink"), thereby inhibiting angiogenesis.[2]

VEGF activity is also regulated by splicing of the corresponding mRNA, which results in the generation of several protein isoforms, including VEGF121, VEGF145, VEGF165, VEGF189, and VEGF206 (designations based on the number of amino acids).[5] These variants differ in their cell association, solubility, the ability to bind heparinoids, or interact with neuropilins, all of which define the formation of extracellular gradients and determine their biologic activity. In this regard, VEGF165 is an especially potent inducer of angiogenesis. VEGF-C and VEGF-D stimulate growth of lymphatics (lymphangiogenesis), via activation of VEGFR3, whereas VEGF-B and PlGF interact with VEGFR1 and are involved in vascular pathologic conditions and inflammation.[2]

Platelet-Derived Growth Factors

The platelet-derived growth factor (PDGF) family of VEGF-related growth factors consists of four members: PDGF-A, PDGF-B, PDGF-C, and PDGF-D, the homodimers or heterodimers of which interact preferentially with one of the three known cellular RTKs, namely PDGFR-α, PDGFR-β, and PDGFR-γ, each endowed with different cellular functions. For example, PDGF-BB is expressed by endothelial cells and mediates their capacity to attract mural cells harboring PDGFR-β.[2]

Prokineticins

This group of factors consists of the endocrine gland–derived vascular endothelial growth factor/prokineticin 1 (EG-VEGF/PK1) and *Bombina variegata*–secreted protein 8/prokineticin 2 (Bv8/PK2), both of which interact with their respective G protein–coupled receptors on endothelial cells (PKR1 and PKR2). These mediators induce VEGF-like effects in endothelial cells and may render tumors resistant to VEGF inhibition.[5]

Angiopoietins and Tie Receptors

Angiopoietins (Ang1, Ang2, and Ang4) interact with the Tie2/TEK receptor (RTK) that is preferentially expressed by endothelial cells and some myeloid cells (see Fig. 13-1). A related orphan receptor, known as Tie1, remains poorly characterized and likely acts by modulating Tie2 activity.[2] Ang1 emanates from perivascular tissues and serves as the main Tie2 agonist to stabilize endothelial-mural cell interactions and to promote endothelial cell survival, vascular quiescence, and the nonpermeable state. Ang2, which is produced by VEGF-stimulated endothelium, exerts the opposite effects and stimulates pericyte detachment, permeability, vascular growth or regression, and lymphangiogenesis.[2]

Notch Pathway

Delta-like (Dll1, 3, and 4) and Jagged (1 and 2) are membrane-bound ligands that activate Notch receptors on adjacent cells. During vascular development and growth Dll4 and Jagged1 are expressed by subsets of endothelial and mural cells, respectively, and regulate their

Table 13-1 Molecular Regulators of Angiogenesis

Regulator	Main Receptor(s)	Biologic Activity
	ANGIOGENIC EFFECTORS CENTRAL TO ENDOTHELIAL AND MURAL CELL FUNCTION	
VEGF-A/VEGF	VEGFR2 (VEGFR3, VEGF1), NRP1	Stimulator of angiogenic functions, migration and survival of ECs, including formation of tip cells
VEGF-C	VEGFR3 (VEGFR2)	Stimulator of angiogenesis (ECs) and lymphangiogenesis (LECs)
Ang1	Tie2	Positive regulator of endothelial-mural interactions, EC survival, and vessel maturation
Ang2	Tie2	Negative regulation of endothelial-mural interactions, stimulator of lymphangiogenesis
Dll4	Notch	Inhibitor of tip cells formation
Jagged1	Notch	Stimulator of tip cell formation
ephrinB2	EphB4	VEGFR internalization/signaling, arterial identity, tube formation
PDGF-B	PDGFR-β	Recruitment of mural cells, vessel maturation
TGFβ1	TGFβRII	Differentiation of mural cells, ECM formation
Integrins (αv, β1, β5)	ECM proteins	EC survival, migration morphogenesis
	STIMULATORS INVOLVED IN PATHOLOGIC ANGIOGENESIS	
PlGF	VEGFR1	Stimulates angiogenesis by interaction with ECs and BMDCs
Acidic FGF (FGF1)	FGFRs 1-4	Stimulator of EC mitogenesis, survival, and angiogenesis
Basic FGF (FGF2)	FGFRs 1-4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF3	FGFRs 1-4	Stimulator of EC mitogenesis, survival, and angiogenesis
FGF4	FGFRs 1-4	Stimulator of EC mitogenesis, survival, and angiogenesis
IL-8	CXCR1	Stimulator of ECs and inflammatory cells
IL-6	IL-6R	Stimulator of inflammatory angiogenesis
TNF-α	TNFR1 (55)	EC stimulator and VEGF inducer
Bv8	GPCR	Stimulator of endocrine and tumor ECs
PD-ECGF/TP	Unclear	Stimulator of angiogenesis
Angiogenin	170-kDa receptor	Stimulator of angiogenesis and RNase
MMP-9	ECM proteins	Matrix metalloproteinase that breaks down ECM and releases angiogenic growth factors
	ENDOGENOUS ANGIOGENESIS INHIBITORS	
Inhibitor	**Biologic Activity**	
TSP1	Interacts with CD36 receptor, integrins, and other proteins causing growth inhibition and apoptosis of angiogenic ECs	
Endostatin	Proteolytic fragment of collagen XVIII with antiangiogenic activity	
Angiostatin	Proteolytic fragment of plasminogen with antiangiogenic activity	
Tumstatin	Proteolytic fragment of collagen IV alpha 3 chain	
sFlt-1/sVEGFR1	Soluble splice variant of VEGFR1 neutralizing VEGF and blocking VEGFR2 signaling	
VEGF165b	Splice variant of VEGF with antiangiogenic activity	
PEX	Inhibitor of EC invasion and MMP activity	
IFN-α (β)	Inhibits release of angiogenic growth factors

distinct functions within the capillary outgrowths (sprouts), as depicted in Figs. 13-2 and 13-3.[14] Dll1 is also involved in circumferential vascular enlargement (arteriogenesis).[2]

Ephrins and Eph Receptors

The arterial or venous identity of endothelial cells in the evolving microcirculation is preprogrammed by the expression of transmembrane guidance molecules, especially ephrinB2 and its EphB4 receptor. Bidirectional signals emanating from these molecules, together with mechanosensory cues, govern the arteriovenous vascular arborization that is essential for, and maintained by, proper blood flow. Other ephrins are implicated in endothelial-pericyte interactions, communication between blood vessels and tumor cells. They may also cooperate in VEGFR2 endocytosis and signaling.[2]

Vascular Integrins, Cadherins, and Cell Adhesion Molecules

Quiescent endothelial cells are anchored to the BM, a structured layer of ECM composed mainly of laminin and collagen type IV. In

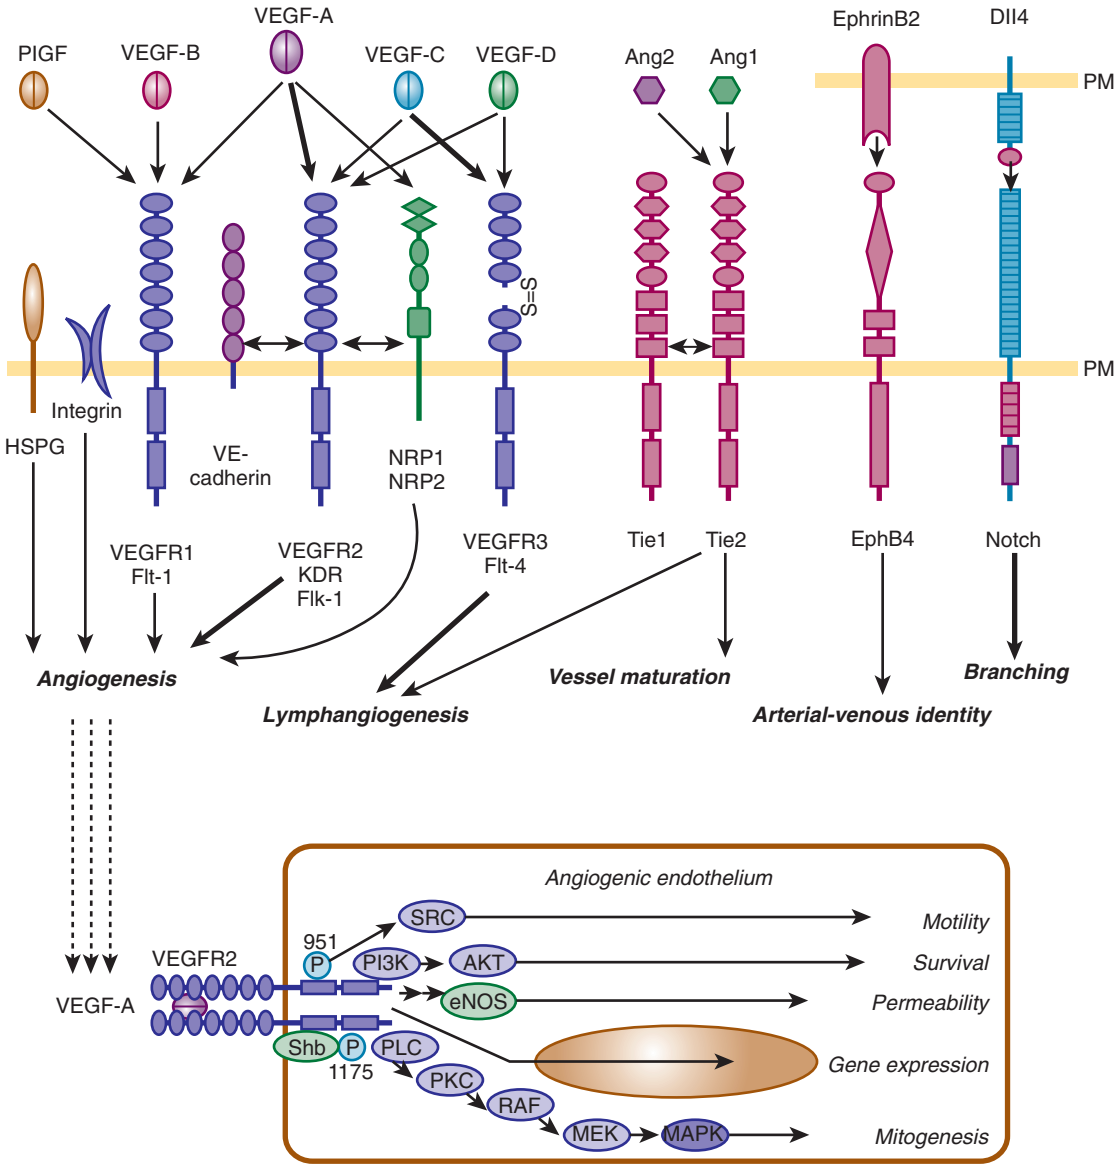

Figure 13-2 Some of the key elements of the signaling circuitry involved in blood vessel formation and tumor angiogenesis. Receptors and coreceptors involved in angiogenic, lymphangiogenic, and regulatory signaling. *Bottom panel:* outline of signaling pathways and their effector mechanisms downstream of VEGF-A/VEGF. *Ang,* Angiopoietin; *Dll,* Delta-like ligand; *eNOS,* endothelial nitric oxide synthase; *HSPG,* heparan sulfate proteoglycan; *NRP,* neuropilin; *PLC,* phospholipase C; *PlGF,* placenta growth factor; *PM,* plasma membrane; *VE-cadherin,* vascular endothelial cadherin; *VEGF,* vascular endothelial growth factor; *VEGFR,* vascular endothelial growth factor receptor.

contrast, growing (angiogenic) endothelial cells are surrounded by provisional ECM containing fibrin, vitronectin, fibronectin, and partially degraded collagens. Growth factors upregulate the expression of dimeric integrin receptors (αvβ3, αvβ5, α1β1, α2β1, α4β1, α5β1), which recognize specific motifs in ECM molecules (often, the RGD sequence). The angiogenesis-related integrin, αvβ3, is the target of blood vessel–directed therapies.

Vascular endothelial cadherin (VE-cadherin/CD144) is selectively expressed by endothelial cells and contributes to their barrier function, homotypic adhesion, and growth regulatory signals. Other cadherins, as well as claudins (e.g., endothelial claudin 5) and connexins, contribute to homotypic and heterotypic endothelial cell interactions, and the formation of gap and tight junctions and transmission of long-range signals that propagate within the vascular wall upstream of the blood flow.[2] On the other hand, interactions between endothelium and circulating immune, myeloid, inflammatory, and progenitor cells, as well as platelets, are mediated by selectins (e.g., P-selectin, L-selectin, and E-selectin), integrins (α4β1/very late antigen 4 [VLA4]), and members of the immunoglobulin family of cell adhesion molecules (intercellular adhesion molecule 1 [ICAM1]/ICAM2 and vascular cell adhesion molecule 1 [VCAM1]), all of which play distinct roles in angiogenesis.[2,15]

Proteases

Proteases regulate remodeling, growth and invasion of new blood vessels, liberation of ECM-bound angiogenic growth factors, generation of regulatory peptides (e.g., angiogenesis inhibitors), clotting and fibrinolysis, intracellular signaling, and numerous other steps involved in vascular maintenance and remodeling. For example, matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs 1 to 4) participate in the controlled ECM/BM breakdown, which is required for invasiveness of the angiogenic endothelium.[15] The key enzymes in this group include MMP-1, MMP-2, MMP-9, and MMP-14, coagulation factors (VIIa and thrombin) and

their receptors (tissue factor and PAR1), urokinase plasminogen activators (uPAs) and their inhibitors (plasminogen activator inhibitor 1 [PAI-1]), members of the disintegrin and metalloproteinase domain and thrombospondin motif–containing families (ADAM and ADAMTS).

Angiogenesis Stimulators and Inhibitors

In addition to "professional" angiogenesis regulators, a number of molecules with more pleiotropic biologic activity serve as stimulators or inhibitors of vascular growth, either directly or indirectly (e.g., as inducers of VEGF). Examples of these diverse effectors are listed in Table 13-1 and include certain cytokines (fibroblast growth factor 1 [FGF1], FGF2, hepatocyte growth factor [HGF], transforming growth factorβ [TGFβ]), chemokines (IL-8/CXCL8, stromal cell–derived factor 1 [SDF-1]/CXCL12), secreted ECM proteins (thrombospondin 1 [TSP1], TSP2), proteolytic ECM fragments (tumstatin, angiostatin), phospholipids (sphingosine-1-phosphate [S1P]), and several other entities.[1] The effects of angiogenesis regulators are mediated by intracellular signaling pathways, including GTPases (Ras), kinases (src, AKT, PKC), transcription factors (ERG, HIF), microRNA species (miR-17, miR-155), and other effectors (see Fig. 13-2).[2]

PROCESSES INVOLVED IN BLOOD VESSEL FORMATION

The vascular system is programmed to rapidly respond to changes in the microenvironment. Although these responses may be provoked by local factors (e.g., tissue injury or hypoxia), they are regulated at several levels, including locally, regionally, and systemically, and with the involvement of perivascular, vessel wall–associated, circulating, and bone marrow–derived cells.[2] These processes are becoming increasingly well defined, and include vasculogenesis, angiogenesis, and lymphangiogenesis, as well as other distinct pathways that lead to increased/changed tissue vascularization (detailed later). For example, expanding parenchyma may orchestrate these events through vascular cooption or intussusception (described later). The vascular wall may undergo remodeling through structural changes, recruitment of pericytes (maturation), or lumen enlargement (arteriogenesis). Distinct mechanisms regulate the regression (pruning) of superfluous capillaries (e.g., during vascular arborization), whereas progenitor cells may mediate vascular repair in the case of endothelial damage (i.e., denudation). New vessel segments may also form when transdifferentiation of nonendothelial stem cells results in the formation of endothelial-like luminal layers (vasculogenic mimicry). Each of these processes is driven by specialized cellular and molecular circuitry and plays a unique role in vascular growth, homeostasis, and pathology, as outlined briefly later.[1,2,5,14]

Vasculogenesis and Vascular Repair

Processes involving the recruitment of endothelial precursors, such as angioblasts or EPCs, and their self-assembly, differentiation, and/or structural integration within the endothelial lining are referred to as vasculogenesis. These events are central to the origin of the vascular system (primary capillary plexus formation) during embryogenesis.[8] Although EPC-like cells can be detected during postnatal life, especially in the bone marrow, walls of large vessels, and in the circulating blood (circulating endothelial progenitors [CEPs]), they have a more restricted role, which is mainly regulatory and reparative in nature. For instance, EPCs may accumulate at sites of angiogenesis, but they rarely form complete vascular segments. However, EPCs may contribute to the endothelialization of denuded luminal surfaces, vascular grafts, or damaged larger vessels (vascular repair) or to the recanalization of occlusive thrombi.[16] Several molecular mechanisms control the recruitment of EPCs and their retention at sites of vascular growth, including high levels of circulating VEGF, SDF-1, expression of certain integrins, and other factors.[4,10]

Angiogenesis

Under conditions of tissue growth, wound repair, hypoxia, or disease (e.g., cancer), new vascular structures emerge from preexisting blood vessels through the process of angiogenesis. Although smaller capillary loops can be generated when the lumens of larger vessels are split by external tissue pillars (intussusception), the main mode of capillary growth involves a mechanism known as *sprouting angiogenesis* (see Fig. 13-3). In this process, a gradient of proangiogenic activity forms around the site of ischemia and triggers a cascade of responses within the wall of the nearest capillary. The reaction begins with local capillary distension to form an enlarged "mother vessel." Although high levels of VEGF are sufficient to induce these changes,[3] the underlying molecular events usually involve a more global shift in levels of multiple angiogenesis inhibitors and stimulators ("angiogenic switch").[1] Some of these factors may upregulate VEGF in parenchymal, stromal, and inflammatory cells or act directly on endothelial cells. Inflammatory cells often cluster at sites of angiogenesis before the formation of new blood vessels, where they contribute to the consolidation of a proangiogenic microenvironment.[2]

The continuous endothelial monolayers (phalanx cells) of mother vessels respond to VEGF by upregulating Ang2, an event that blocks the tonic activation of the Tie2 receptor by the constitutive presence of Ang1. This disrupts the key mechanism maintaining capillary structure and leads to detachment of pericytes, followed by local dissolution of the BM (by MMPs) and other events, such as an increase in vascular permeability and extravasation of plasma proteins. The extravascular deposition of fibrin and the formation of a provisional ECM provide the scaffold for the formation of new capillaries.[2]

These processes liberate endothelial cells and instruct some of them to emigrate from the activated vascular segment in an orderly fashion. Such migration occurs in the form of a directional cellular column known as an angiogenic sprout (see Fig. 13-3). Each sprout is composed of a single, specialized leading endothelial cell (tip cell) equipped with hair-like, sensing projections (filopodia), which contain high concentrations of VEGFR2 and are rich in other regulators (e.g., PDGF-B, SDF-1, Apelin, and Dll4). In their gradient-seeking movement, tip cells are followed by a cohort of endothelial stalk cells, which express VEGFR1 and Notch, and are capable of proliferation. Stronger stimulation by VEGF results in VEGFR2-dependent upregulation of Dll4 in tip cells and allows them to instruct their stalk cell counterparts (via Notch) to retain their phenotype, refrain from independent branching, and maintain VEGF signaling at lower levels. The latter is mediated, at least in part, by upregulation of soluble VEGFR1 (the "VEGF sink" molecule). Consequently, the exogenous blockade of the Dll4/Notch pathway leads to excessive generation of tip cells and sprouts (from stalk cells), resulting in the formation of overly branched, hyperdense, nonperfused, and dysfunctional capillary network ("non-productive angiogenesis").[14] Stimulation of Notch by Jagged1 ligand modulates the effects of Dll4 on stalk cells and fine-tunes the branching pattern. The neighboring sprouts eventually connect (anastomose) to form new capillary loops. This process is mediated by interaction with tissue macrophages expressing Tie2 and NRP1.[17] Subsequent generation of the vascular lumen and resumption of blood flow occur through formation of intercellular spaces between endothelial stalk cells.[2]

Vascular Maturation

Maturation of vessels involves a buildup of a mural cell layer around the newly formed endothelial tube and is driven by several molecular mechanisms.[2] Thus endothelial tip cells secrete PDGF-B, which attracts regional pericytes, which provide structural support and vessel-stabilizing Ang1 activity.[18] S1P regulates N-cadherin, which further links endothelial cells and pericytes. Upon their attachment to the endothelial tube, pericytes assume a more mature phenotype

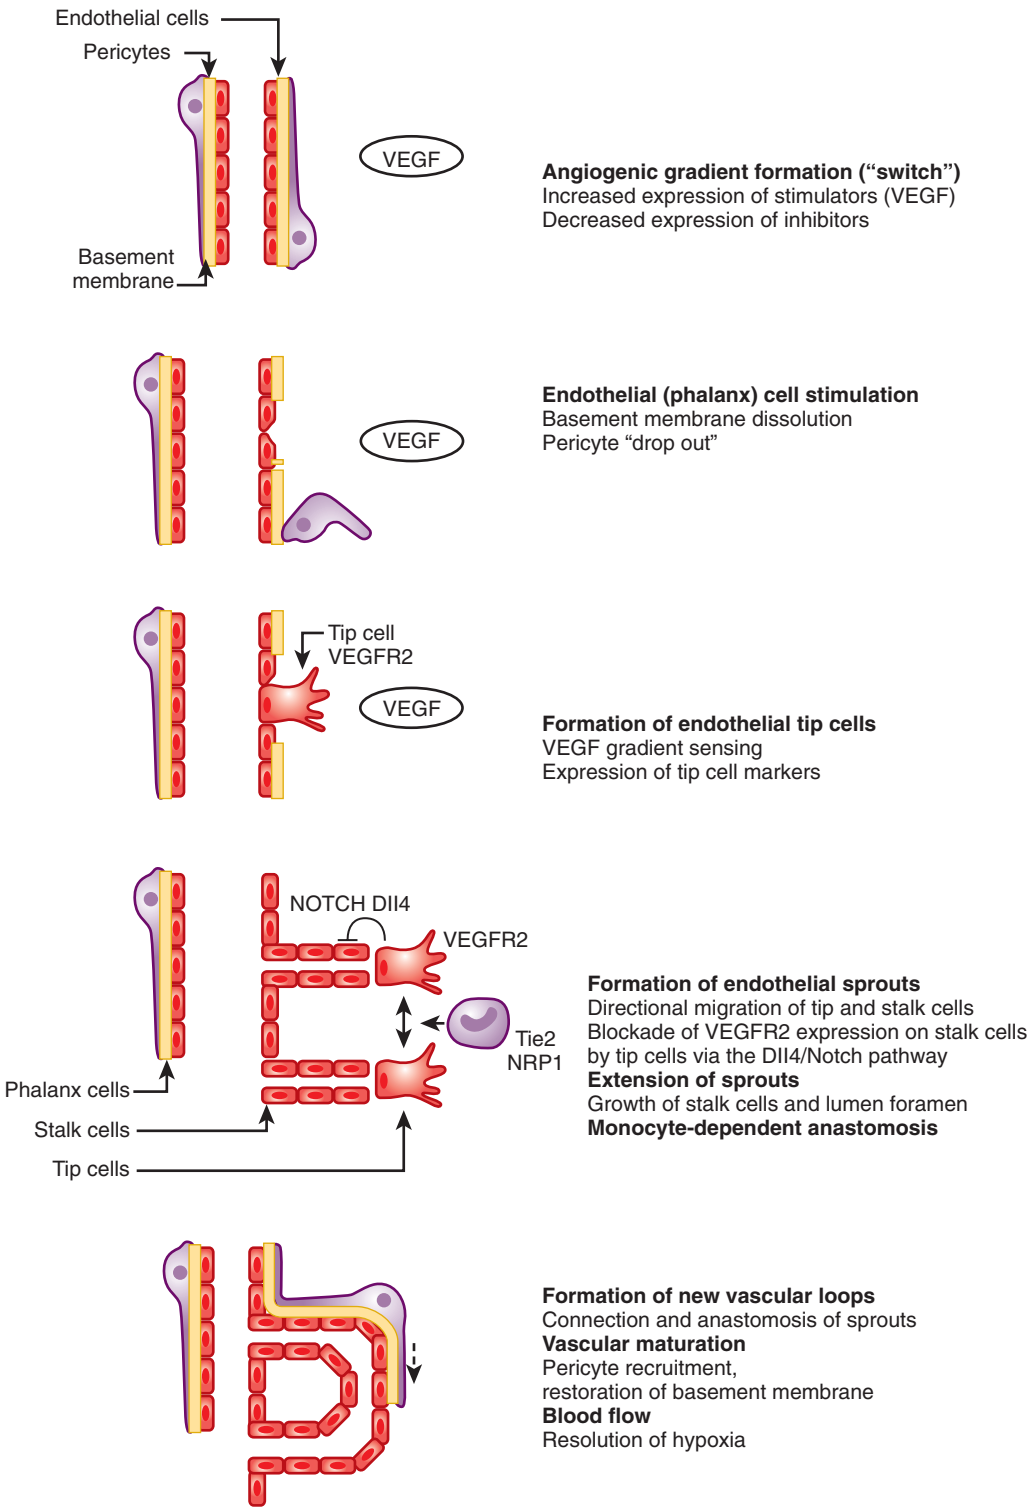

Figure 13-3 SPROUTING ANGIOGENESIS. The change in balance between angiogenesis stimulators and inhibitors (angiogenic switch) and especially gradient of vascular endothelial growth factor (VEGF) leads to sprouting angiogenesis. This causes changes in the vessel wall (endothelial phalanx cells) resulting in formation of mother vessels, endothelial tip cells, stalk cells, capillary loops, and eventually anastomoses, as depicted (details are in the text and in Carmeliet and Jain[2]). *Dll,* Delta-like ligand; *NRP,* neuropilin; *VEGFR,* vascular endothelial growth factor receptor.

under the influence of TGFβ1.[18] Endothelial prolyl hydroxylase 2 (PHD2), an oxygen-sensing enzyme, also regulates pericyte recruitment. These mechanisms ensure vascular integrity, mechanical resistance, endothelial cell survival, diminished dependence on VEGF, and restricted permeability.[2]

Lymphangiogenesis

As mentioned earlier, sprouting of new lymphatics is described as lymphangiogenesis. LECs express distinct markers (VEGFR3, Prox-1, LYVE-1) but otherwise exhibit up to 98% molecular similarity to

their vascular counterparts (VECs). Upon stimulation by VEGF-C, VEGF-D, VEGF, and Ang2 (which acts as a Tie2 agonist in LECs and a Tie2 antagonist in VECs), LECs form networks of thin-walled vessels that serve as conduits for collection of interstitial fluid and cells, including inflammatory cells and metastatic cancer cells.[19]

Vasculogenic Mimicry

In some instances, multipotential, nonendothelial cells may adopt an endothelial-like phenotype and can line vascular channels.[20] This process, which is termed *vasculogenic mimicry,* occurs during normal placentation and in tumors, such as melanoma, mouse teratoma, and in certain regions of human glioblastoma, where cancer stem cells undergo such endothelial transdifferentiation.[20]

Vascular Cooption

Cancer cells may grow around, envelop, and exploit preexisting vessels.[21] This process is observed in highly vascular organs, such as the lung and brain, and is referred to as *cooption.* Coopted vessels may undergo additional structural alterations, which may result in remodeling and the formation of occlusive thrombi and regression that can lead to ischemia.[22]

MECHANISMS TRIGGERING ANGIOGENESIS

Vascular growth may occur in response to hypoxia, growth factors, inflammatory mediators, activation of the coagulation system, and after malignant transformation. These mechanisms converge upon the regulation of the VEGF gene[5] but also involve complex networks of other effectors, which may exhibit context-dependent degrees of functional redundancy.[2] VEGF is transcriptionally regulated by dimeric HIF1 and HIF2 factors. Normally, the HIF alpha subunit (HIF-1α) is constitutively degraded by a pathway involving oxygen-dependent prolyl and asparaginyl hydroxylases, von Hippel-Lindau (VHL) ubiquitin ligase, and the proteasome.[23] Hypoxia blocks this process, resulting in increased HIF activity and VEGF production by parenchymal, stromal, and inflammatory cells. Several other mechanisms of proangiogenic, hypoxic responses have also been described (e.g., NFκB, EGR1).[24] Likewise, the exposure of cells to growth factors (epidermal growth factor [EGF], FGF, HGF) and inflammatory cytokines (IL-6) may upregulate VEGF, and some of these effectors may also directly stimulate endothelial cells.[2] Activation of oncogenes (e.g., Ras) and loss of tumor suppressors (VHL) lead to upregulation of VEGF and may also affect other angiogenic growth factors in cancer cells, even under conditions of normoxia.[9] Oncogenic transformation also shuts down some of the angiogenic inhibitors, contributes to coagulopathy (through upregulation of tissue factor and thrombin receptors), and enhances proangiogenic cellular vesiculation. Indeed oncogenic pathways often mimic, distort, or exacerbate the effects of hypoxia.[9]

THERAPEUTIC IMPLICATIONS OF ANGIOGENESIS IN HEMATOLOGY

Vascular events associated with cancer, hemangioma, or vascular malformation have the potential to trigger hematologic consequences, either spontaneously or during therapeutic angiogenesis or antiangiogenesis. These linkages are poorly understood but often include one or more of the following factors: (1) endothelial cell activation associated with intravascular upregulation of tissue factor, adhesion molecules, and other factors; (2) disruption of the vascular wall; (3) recruitment of inflammatory cells and BMDCs (e.g., by cytokines); (4) enhanced vascular permeability, resulting in the extravasation and activation of coagulation factors; (5) platelet activation; (6) contact between procoagulant cells (e.g., metastatic cancer cells) and circulating blood; (7) flow perturbations and stasis; (8) indirect external effects (e.g., indwelling catheters or administration of chemotherapy); and several other factors.[9] Nonetheless, understanding the impact of blood vessel–directed therapies, which can modulate or exacerbate some of these events, represents a new direction in hematology.

Therapeutic Inhibition and Stimulation of Angiogenesis

Excessive, protracted, or aberrant activation of vascular growth may represent a correlative and/or a causative factor in several pathologic conditions (often referred to collectively as *angiogenesis-related diseases*).[1] These include chronic inflammation, certain forms of blindness, metabolic diseases, atherosclerosis, and cancer.[1] In some of these disorders (e.g., macular degeneration, certain malignancies) antiangiogenic therapies, especially inhibitors of the VEGF pathway (Table 13-2), already represent the standard of care. Numerous clinical trials are ongoing to explore other agents and indications.[2]

Conversely, pathologic conditions may also arise because of insufficient angiogenesis, arteriogenesis, or regulatory/repopulating activity of BMDCs, as is the case in the myocardium after infarction, in limb ischemia, and in other hypovascular states, especially in elderly persons. In these disorders, stimulation of vascular growth may provide a therapeutic benefit, notably through delivery of angiogenic cells (EPCs), growth factors (VEGF, FGF), or gene therapy vectors into the affected site. Several such (proangiogenic) strategies are currently under investigation.[2]

Tumor Angiogenesis and Antiangiogenesis

The disorganized signaling cues that occur during tumor angiogenesis may produce highly abnormal, leaky, tortuous, prothrombotic, and poorly perfused vasculature (vessel "abnormalization"), which may contribute to aberrant hemostasis.[2] Antiangiogenic agents may cause further perturbations by targeting the related molecular anomalies. These agents are aimed at either selective destruction of tumor-associated endothelial cells or at inhibition of their stimulatory circuitry.[1] Several classes of antiangiogenic compounds have been scrutinized to date, including derivatives of natural angiogenesis inhibitors (e.g., endostatin or tumstatin), inhibitors of proangiogenic signaling pathways (antibodies, small molecule agents), and agents that block proangiogenic inflammatory pathways (e.g., thalidomide). Anticancer drugs may also be administered in low but frequent doses (metronomic chemotherapy) to preferentially target endothelial cells (see Table 13-2).[1,4,25]

Bevacizumab (Avastin), a humanized monoclonal anti-VEGF antibody was the first antiangiogenic agent to be developed and approved (in 2004) for cancer treatment, and the drug is now used to treat colorectal, lung, kidney, and brain tumors.[2] Several multikinase inhibitors with anti-VEGFR activity (sunitinib, sorafenib, pazopanib) are also in common use, as are inhibitors of oncogenic pathways that drive the production of VEGF.[9] The latter include inhibitors of the epidermal growth factor receptor (EGFR) and human epidermal growth factor receptor 2 (HER2) (cetuximab and trastuzumab, respectively), and other oncogene inhibitors.[9] These VEGF/VEGFR antagonists are mostly used in combination with chemotherapy, which suggests that they serve as chemosensitizers.[4] Studies are under way to develop drugs that specifically target pathologic angiogenesis (e.g., blockers of PlGF), or established tumor blood vessels (e.g., vascular disrupting agents [VDAs]).[4]

The overall objective of antiangiogenic therapy in cancer is to induce tumor hypovascularity, thereby causing hypoxic damage to tumor cells. Of note, blockade of Dll4 may result in hypoxia through a process that involves "nonproductive" angiogenesis and tumor hypervascularity.[14] Alternatively, antiangiogenic agents may also induce "vessel normalization" and improved tumor perfusion, which can lead to increased sensitivity to chemotherapy and radiation.[2]

Table 13-2 Blood Vessel–Targeting Agents: Antiangiogenic Agents

Drug	Type	Target	Stage of Development
TARGETED AGENTS DESIGNED TO OBLITERATE DEFINED ANGIOGENIC PATHWAYS			
Bevacizumab (Avastin)	Neutralizing huMoAb	VEGF	Approved for human use
Sunitinib (Sutent)	TKI	VEGFR1-3, PDGFR-α/β, KIT, Flt-3, RET, CSF1R	Approved for human use
Sorafenib (Nexavar)	TKI	VEGFR2-3, C-Raf, B-Raf, VEGF-C, Flt-3, FGFR1, PDGFR-β, KIT, p38	Approved for human use
Pazopanib (Votrient)	TKI	VEGFR1-3; PDGFR-α/β; KIT; FGFR1, 3, 4; FMS	Approved for human use
Vandetanib (Caprelsa) ZD6474	TKI	VEGFR2, EGFR, RET	Approved for human use
Axitinib (AG-013736)	TKI	VEGFR1-3, PDGFR, KIT	Approved for human use
XL184	TKI	VEGFR2, MET, RET, KIT, Flt-3, Tie2	In clinical development
VEGF Trap (Aflibercept)	Soluble VEGF "receptor-body"	VEGF-A, -B, PlGF	Approved for human use
Cilengitide	Cyclic peptide	αvβ3/β5 Integrin	In advanced clinical trials
AGENTS WITH DIRECT ANTIANGIOGENIC ACTIVITY			
Endostar	Protein fragment	Unclear	In human use (China)
ABT-510	Peptide	Endothelial CD36	In clinical development
2ME2	Sterol	HIF-1α, tubulin	Investigational agent
TNP-470 (Lodamin)	Small molecule (slow release)	Complex activity	Investigational agent
INDIRECT-ACTING AGENTS DESIGNED TO BLOCK ONCOGENIC PATHWAYS DRIVING ANGIOGENESIS			
Trastuzumab (Herceptin)	Neutralizing huMoAb	HER2	Approved for human use
Cetuximab (Erbitux)	Neutralizing huMoAb	EGFR	Approved for human use
Gefitinib (Iressa)	TKI	EGFR	Approved for human use
Erlotinib (Tarceva)	TKI	EGFR	Approved for human use
Lapatinib (Tykerb)	TKI	EGFR, HER2	Approved for human use
Imatinib (Gleevec)	TKI	ABL, PDGFR-β, KIT	Approved for human use
PF-00299804	TKI	Irreversible pan-ErbB inhibitor	In development
Tipifarnib	FTI	Ras, farnesylated proteins	In clinical development
AGENTS WITH ANTIANGIOGENIC AND NONANTIANGIOGENIC ACTIVITIES			
Chemotherapy (metronomic)	Various agents (CTX, VBL, TMZ, TAX)	Stress response pathways, DNA, cytoskeleton	Under clinical exploration
Celecoxib (Celebrex)	Small molecule	COX-2	Under clinical exploration
Thalidomide and analogues (lenalidomide)	Small molecule	Inflammatory pathways	Approved in multiple myeloma, under investigation
ANTIVASCULAR AGENTS/VASCULAR DISRUPTING AGENTS			
ASA404	Flavonoid	EC survival	Advanced clinical trials
CA4P	Tubulin binding	Tubulin assembly	Advanced clinical trials
AVE8062	Tubulin binding	Tubulin assembly	Advanced clinical trials
ABT-751	Tubulin binding	Tubulin assembly	Advanced clinical trials
OXi4503	Tubulin binding	Tubulin assembly	In clinical trials

COX-2, Cyclooxygenase-2; *CSF1R,* colony-stimulating factor 1 receptor; *CTX,* cyclophosphamide; *DNA,* deoxyribonucleic acid; *EGFR,* epidermal growth factor receptor; *FGFR,* fibroblast growth factor receptor; *FTI,* farnesyltransferase inhibitor; *HER2,* human epidermal growth factor receptor 2; *HIF-1α,* hypoxia-inducible factor-1α; *huMoAb,* humanized monoclonal antibody; *2ME2,* 2-methoxyestradiol; *PDGFR,* platelet-derived growth factor receptor; *PlGF,* placenta growth factor; *TAX,* paclitaxel; *TKI,* tyrosine kinase inhibitor; *TMZ,* temozolomide; *VBL,* vinblastine; *VEGF,* vascular endothelial growth factor; *VEGFR,* vascular endothelial growth factor receptor; see text and references for more details.[2]

Angiogenesis and Antiangiogenesis in Hematopoietic Malignancies

The vascular bone marrow stroma plays a pivotal role in leukemogenesis. Indeed, angiogenesis, increased vascular density, and increased levels of angiogenic growth factors have all been observed in the bone marrow of patients with hematopoietic malignancies.[26] VEGF may play multiple roles in this context, including as a (1) vascular growth stimulator, (2) paracrine growth factor for leukemic stem cells,[7] and (3) inducer of angiocrine interactions between these cells and the

endothelium.[27] Consequently, a wide spectrum of antiangiogenic agents, including VEGF antagonists (bevacizumab, sorafenib, sunitinib, cediranib) are now being investigated for the treatment of hematologic disorders such as acute myeloid leukemia, chronic myeloid leukemia, acute lymphoblastic leukemia, myelodysplastic syndrome, non-Hodgkin lymphoma, multiple myeloma, and others.[7] Additional agents with antiangiogenic activity have also been explored (bortezomib), but the antiinflammatory antiangiogenics (thalidomide and lenalidomide) are the only drugs to be licensed thus far (in multiple myeloma and myelodysplastic syndrome, see Medinger and Mross[7] for review).

Hematologic Complications Associated With Blood Vessel–Directed Agents

Manipulation of endothelial and mural cells in the course of proangiogenic and antiangiogenic therapy creates the potential for side effects.[28] The most extensive clinical experience is in the area of cancer, where some toxicities (e.g., hypertension, proteinuria, fatigue, hypothyroidism), have been observed, along with hematologic side effects, mainly thrombosis and/or bleeding. Although cancer patients are prone to thrombosis,[29] additional risk for venous and arterial thromboembolism may also be associated with antiangiogenic therapy.[6] A considerable variability in this regard has been reported with different agents, and their effects found to be exacerbated by the accompanying chemotherapy or hormonal therapy.[29] This is of particular concern in patients with multiple myeloma who receive thalidomide derivatives in combination with anthracyclines and dexamethasone. In this case the reported risk for thrombosis could be as high as 75%.[29] Bevacizumab may also provoke an up to twofold increase in arterial thrombosis in patients with solid tumors, especially in the presence of additional risk factors and old age. These estimates are variable, however (0.9% to 19.4% according to different studies), and drug specific, because small-molecule kinase inhibitors acting on VEGFR are less likely to trigger venous thromboembolism (0% to 3%).[29]

Bleeding episodes were also recorded with several of these agents, ranging from minor to life threatening.[30] In general, however, antiangiogenic agents are relatively well tolerated, and their side effects are usually manageable with careful monitoring and standard supportive care[6] (see box on Advantages, Disadvantages, and Resistance to Antiangiogenic Therapy in Cancer).

Advantages, Disadvantages, and Resistance to Antiangiogenic Therapy in Cancer

Advantages of Antiangiogenesis
- Is directed against unique molecular targets
- Interferes with unusual deregulation of vascular cells and has moderate toxicity
- Targets the "angiocrine" niche for cancer and leukemic stem cells
- The target (blood vessels) is readily accessible to therapeutics
- Targets a rate-limiting process for tumor growth and dissemination
- Circumvents certain forms of drug resistance in cancer
- In some cases resistance to antiangiogenics is reversible
- Improves the efficacy of chemotherapy and radiation (vessel "normalization")

Disadvantages of Antiangiogenesis
- May facilitate hypoxic selection of more aggressive cancer cells
- May provoke cytokine emission and reactive bone marrow mobilization
- Bone marrow activation and pericyte damage may stimulate invasion and metastasis
- May cause toxicity related to housekeeping effects of angiogenic factors (e.g., vascular endothelial growth factor)
- Causes vessel regression and may activate coagulation
- May compromise wound healing
- May cause some unspecific toxicities

Mechanisms of Resistance to Antiangiogenic Agents
- Oncogenic mutations in cancer cells rendering them refractory to ischemia
- Redundancy of proangiogenic pathways in cancer cells ("evasive" resistance)
- Influx of proangiogenic host cells (fibroblasts, myeloid cells)
- Formation of more mature (pericyte-rich) vessels
- Onset of alternative modes of neovascularization (cooption, vasculogenic mimicry)
- Rapid vascular regrowth
- Genetic alterations in tumor endothelial cells
- Rebound effects involving angiogenesis, lymphangiogenesis, invasion, and metastasis

FUTURE DIRECTIONS

The functional integration of the vascular system, bone marrow, and circulating blood results in a high degree of biologic interdependence. Although this may not always be clinically obvious, the existence of these subtle links necessitates a greater inclusion of blood vessel–regulating processes into pathogenetic analysis and therapy of hematologic disorders.

CHAPTER 14

PRINCIPLES OF CYTOKINE SIGNALING

Monteaser Shaheen and Hal E. Broxmeyer

CYTOKINE AND RECEPTOR FAMILIES AND SIGNAL TRANSDUCTION

Cytokines are secreted molecules that regulate cellular interactions through binding to defined receptors and inducing intracellular signaling. Cytokines are classified based on the primary structural features of the extracellular domains of their receptors.[1] Class or type I cytokines (often referred to as *hematopoietins*) regulate development, differentiation, and activation of hematopoietic and immune cells. Type I cytokine receptors include those for colony-stimulating factors (CSFs), interleukins (ILs), erythropoietin (EPO), thrombopoietin (TPO), and some hormones such as growth hormone and leptin. Class II cytokines consists of type I interferons (IFNs), including IFN-α, IFN-β, IFN-ω, IFN-ε, IFN-κ, IFN-τ, IFN-ς/lumitin, IFN-δ and IFN-ν, type II IFN consisting of the single IFN-γ, and the IL-10 family of cytokines (which includes several cytokines, including IL-19, IL-20, IL-22, IL-24, IL-26) and type III IFNs, including IFN-λ1 (IL-29), IFN-λ2 (IL-28A), and IFN-λ3 (IL-28).

The structural similarities of type I cytokines were not initially recognized. However, cloning of their receptors revealed significant homology in that the extracellular regions contain a common domain with four conserved cysteines (C4) in the N-terminal segment and a tryptophan-serine doublet near the C-terminal end.[2] This 200–amino acid region, which is derived from a tandem of two fibronectin-like domains, has been named the *hematopoietin receptor domain*. Two conserved Box1/Box2 regions are located in the proximal intracytoplasmic segment. Fig. 14-1 depicts the general structure of a type 1 cytokine receptor. By contrast, type II cytokine receptors contain two cysteine doublets (C2-C2) located in the C-terminal end of both fibronectin-derived domains. They retain Box1/2 regions but lack the tryptophan(Trp)-serine(ser)-x(any amino acid)-serine(ser)-tryptophan(Trp) motif. Both types of receptors bind ligands that display common spatial four α-helix bundle organization and utilize intracellular signaling mediators of the Janus kinase (JAK) and signal transducer and activator of transcription (STAT) families. Because of these shared features, type I and II cytokine receptors represent a homogeneous structural group of proteins. However, sequence homology is observed in a limited number of cases, such as for the growth hormone (GH)/prolactin (PRL) family and for the IL-6 family. Nonetheless, evidence of common ancestry of cytokines can be observed in the similar four-helix bundle structure[3] in addition to the similar intron–exon relationship and the clustering observed for certain cytokine genes such as genes of the IL-4 family.[4]

The receptors can be composed of dimers of a single chain (granulocyte-colony stimulating factor receptor [G-CSFR], EPO receptor [EPOR], TPO receptor [TPOR or c-mpl]) or can be heterodimeric with a common signaling subunit and a unique ligand-binding chain. These heterodimeric receptors can be grouped into families based on whether they share the common β-chain (granulocyte macrophage [GM]-CSFRα, IL-3Rα, IL-5Rα) or those that share the gp130 receptor (IL-6Rα, leukemia inhibitory factor receptor β, ciliary neurotrophic factor receptor α, IL-11Rα, oncostatin M receptor α, cardiotrophin-like cytokine factor 1) and those that share the common γ-chain (IL-2Rα, IL-2R β, IL-4Rα, IL-7Rα, IL-9Rα, IL-13Rα, IL-15Rα, and IL-21Rα). Fig. 14-2 demonstrates the shared receptors' units among type 1 cytokine receptor families. Cytokines bind their cognate receptors with high affinity. This binding triggers receptor homodimerization (e.g., G-CSFR), heterodimerization or oligomerization of receptor subunits (e.g., granulocyte macrophage colony-stimulating factor receptor [GM-CSFR]), or it induces a conformational change in preformed receptor dimers (EPOR), resulting in the activation of the JAKs. Unlike other receptors with intrinsic enzyme activity (e.g., receptor tyrosine kinases [RTKs] such as Flt3 and c-Kit), most cytokine receptors are constitutively associated with kinases. These cytoplasmic kinases comprise the four members of the JAK family: JAK1, JAK2, and tyrosine kinase 2 (Tyk2), which bind to a wide range of receptors, and JAK3, which binds to only one receptor, the common gamma chain, or γc. This binding is mediated by interactions between the 4.1, ezrin, radixin, moesin (FERM) domain of JAK and the Box1 membrane proximal intracytoplasmic region of the receptor. Upon ligand binding, JAKs come into juxtaposition and phosphorylate themselves and their associated receptors. Mutagenesis studies have shown that there are distinct regions of individual phosphorylated receptors that transmit signals for cell survival, proliferation, differentiation, or activation via interaction with adaptor molecules. Phosphorylation of certain residues generates docking sites for the Src homology (SH2) domains of the STATs. After bound to the receptor–JAK complex, STATs are themselves phosphorylated, which induces a conformational change that generates active STAT dimers via reciprocal phosphotyrosine and SH2 domain interaction. The dimers translocate to the nucleus, where they bind to DNA sequences in the promoters of target genes to activate transcription.

Multiple mechanisms exist to attenuate cytokine signaling, which ensures controlled cellular responses to cytokines and prevents pathologic hyperactivation. Because the signaling is mediated by extensive phosphorylation, phosphatases have emerged as important negative regulators. Examples of these include the Src-homology 2 containing phosphatase (SHP) proteins. Other regulators have been identified including protein inhibitors of activated STAT (PIAS), suppressor of cytokine signaling (SOCS) proteins, and cytokine-inducible SH2-domain-containing proteins (CIS). Fig. 14-3 simplifies the intracellular events that are triggered by cytokine-receptor engagement. This chapter discusses in some details the proposed mechanisms of inhibition of these proteins. Expression of receptors is also regulated at the level of gene transcription, protein translation, internalization, and degradation.

MODELS OF LIGAND-RECEPTOR BINDING AND ACTIVATION

Cytokines bind with high affinity to their cognate receptors. The presence and the density of the receptors may determine the biologic response in a hematopoietic progenitor or lymphocytic cell population.[5] The crystal structures of cytokines bound to the receptors have been illustrated for multiple cytokine families. It can be concluded, for most cytokine–receptor couples, that more than one cytokine molecule engages more than one receptor unit at one time to form a complex. For example, two IL-6 molecules aggregate with four receptor chains to form a hexameric and interlocking assembly

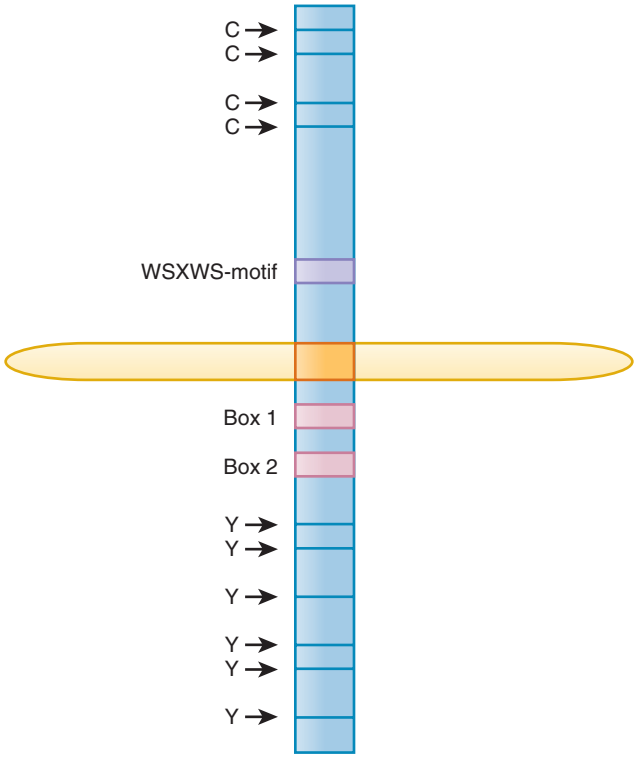

Figure 14-1 CYTOKINE RECEPTOR SUPERFAMILY. The general structure of cytokine receptor superfamily. In the extracellular cytokine receptor module (CRM) 4 conserved cysteine residues exist and are involved in disulfide bonds. A WSXWS (Trp, Ser, any, Trp, Ser) motif that is essential for receptor processing, ligand binding, and activation of the receptor is also located in the extracellular domain. In the intracellular portion, two short domains termed *box 1* and *box 2* are important for Janus kinase (JAK) binding. Tyrosine residues are present on the intracellular part to be phosphorylated upon receptor activation.

mediated by a total of 10 symmetry-related, thermodynamically coupled interfaces.[6] The assembly of this hexameric complex occurs sequentially: IL-6 is first engaged by IL-6Rα and then is presented to gp130 in the proper geometry to facilitate a cooperative transition into the high-affinity, signaling-competent hexamer (Fig. 14-4). This structure also reveals that gp130 is bent such that the membrane-proximal domains of gp130 are close together at the cell surface, enabling activation of intracellular signaling. Variation in the receptor bend angles suggests a possible conformational transition from open to closed states upon ligand binding. Reconstruction of full-length JAK1 in conjunction with gp130/IL–6/IL–6Rα complex reveals a three-lobed structure of JAK1 possessing extensive intersegmental flexibility that likely facilitates allosteric activation[7] (Fig. 14-5). Single-particle imaging of the gp130/IL–6/IL–6Rα/JAK1 holocomplex shows JAK1 associated with the membrane proximal intracellular regions of gp130, abutting the would-be inner leaflet of the cell membrane. JAK1 association with gp130 appears to be enhanced by the presence of a membrane environment.

It has been debated how the 16 human type I IFN molecules signal through the same receptors, IFNAR1 and IFNAR2, yet they can evoke different physiologic effects. Recently, structural analysis of this family in complex with this single receptor complex indicates that the receptor–ligand cross-reactivity is enabled by conserved receptor-ligand "anchor points" interspersed among ligand-specific interactions that "tune" the relative IFN-binding affinities in an apparent extracellular "ligand proofreading" mechanism that modulates biologic activity.[8] This differential binding leads to variable conformational changes in the receptor complex, resulting in different STAT phosphorylation profiles, receptor internalization rates, and downstream gene expression patterns.

Signaling networks are typically measured in either their basal (minimum) or hyperstimulated (maximum) states. Recent investigations[9] indicate that the cytokine signal "dynamic range," defined as the responsiveness of cell outcomes to incremental changes in signal activation is more important for biologic outcome than signal strength per se.

The following describes information on JAK and STAT proteins. Table 14-1 summarizes the abnormalities in mice associated with deletion of specific JAK and STAT genes.

Janus Kinases

Janus kinase proteins are Tyks of approximately 1000 amino acids. They have clear nonredundant in vivo functions defined by the analysis of gene deletion in mice and mutations of JAK3 or Tyk2 in humans that lead to primary immunodeficiency syndromes of severe combined immunodeficiency (SCID) type and autosomal recessive hyperimmunoglobulin E syndrome (AR-HIES), respectively.[10] In addition, somatic mutations of JAKs are seen in human neoplastic conditions. Below is a brief description of functions of the JAKs in cytokine signaling. Fig. 14-6 depicts the general structure of JAK proteins.

Janus Kinase 1

Janus kinase 1 is widely expressed and associates with the IFN receptors and receptors that use gp130 or γ chain (γc). JAK1$^{-/-}$ mice have grossly normal nonlymphoid organogenesis[10,11]; however, the neonates fail to nurse and die perinatally of a poorly characterized defect that may be neurologic. It is believed that this morbid phenotype is attributable to the failure of signaling via cytokines that promote neuronal cell survival via gp130. Defective cytokine signaling is observed with class II cytokine receptors (IFNs) and IL-2, IL-6, and IL-7 families. There is a severe lymphocyte defect in the newborn mice consistent with the fact that JAK1 binds to the ligand-specific receptor subunit of γc. Somatic JAK1 activating mutations have been described in occasional cases of acute leukemia and solid tumors.

Janus Kinase 2

Janus kinase 2 is widely expressed and is involved in signaling by single-chain hormone receptors, the common β chain family, and certain members of the class II receptor cytokine family. JAK2 deficiency is lethal at day 12.5 because of failure of erythropoiesis,[12] and this explains lack of reports on individuals with germline loss-of-function JAK2 mutations. Receptor stimulation by EPO induces tyrosine phosphorylation of JAK2, which is required for EPO function.[13] Defective responses of cells from JAK2$^{-/-}$ mice also reveal its essential role in the signaling of IL-3, GM-CSF, IL-5, TPO, and IFN-γ but not IL-6 and IFN-α/β.[14] Transfer of JAK2$^{-/-}$ fetal liver cells into irradiated JAK3$^{-/-}$ recipients resulted in normal thymic subsets, arguing that JAK2 is not essential for T-cell development. In 2005, multiple groups identified activating mutations in JAK2 as the etiology for virtually all cases of polycythemia vera, and significant percentages of cases of essential thrombocythemia and idiopathic myelofibrosis. JAK2 mutations have also been described in other hematopoietic neoplasms. JAK2 inhibitors have shown efficacy at least in decreasing spleen size and constitutional symptoms in patients with JAK2 mutation–positive myeloproliferative disorders.

Janus Kinase 3

In contrast to the ubiquitous expression of the other JAKs, JAK3 is predominantly expressed in hematopoietic tissues. JAK3 selectively associates exclusively with the γc, which is a component of multiple

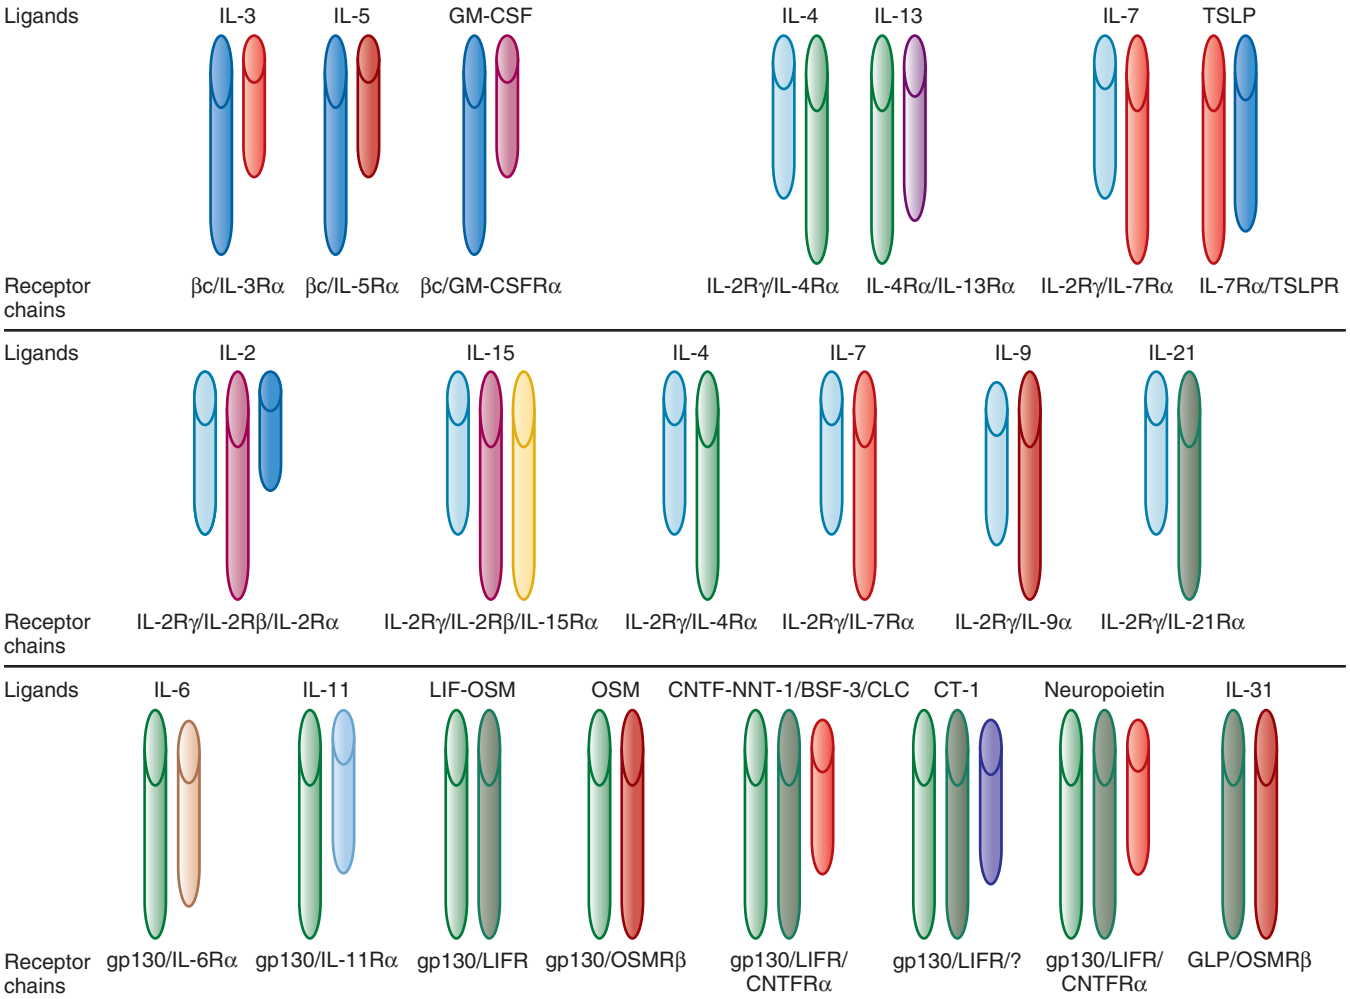

Figure 14-2 SIMPLE DEPICTION OF TYPE 1 CYTOKINE RECEPTOR SUBFAMILIES THAT SHARE RECEPTOR UNITS. Interleukin-3R (IL-3R), IL-5R, and granulocyte macrophage colony-stimulating factor receptor (GM-CSFR) share a common βc chain that place them in one group. Multiple cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21) share the IL-2Rγ chain, which is mutated in a subset of patients with severe combined immunodeficiency. IL-4R shares a subunit with IL-13R. Both IL-4 and IL-13 drive Th2 response. IL-7R shares one subunit with the thymic stromal lymphopoietin (TSLP). This sharing of receptor subunit may explain why deletion of the gene encoding IL-7R affects the lymphoid system more severely than deleting the IL-7 gene. Finally, the IL-6 family includes multiple cytokines that all share the common signal transducer gp130. Deleting gp130 results in embryonic lethality. Some IL-6 family members activate more than one receptor. Oncostatin M (OSM) can work through a heterodimer receptor consisting of gp130 with OSMRβ or gp130 with leukemia inhibitory factor receptor (LIF-R). Ciliary neurotrophic factor (CNTF) shares its receptor with novel neurotrophic-1/B cell–stimulating factor-3/cardiotrophin-like cytokine (NNT/BSF-3/CLC). Cardiotrophin-1 (CT-1) uses a receptor composed of gp130, LIF-R, and another yet to be identified subunit. Neuropoietin shares the same receptor as CNTF. IL-31 receptor is composed of gp130-like receptor (GLR) and OSMRβ.

cytokine receptors. Accordingly, a mutation of γc or JAK3 results in SCID in humans, characterized by the lack of T and natural killer (NK) cells, but B-cell numbers are preserved; thus, this abnormality is designated T^-B^+ NK^- SCID.[15] Mice homozygous for JAK3 null mutation have severe defects in lymphoid cells. B-cell precursors in bone marrow, thymocytes, and both T and B cells are drastically decreased,[10] although these defects can improve as aging occurs.[16] Peripheral lymph nodes, NK cells, dendritic cells (DCs), epidermal T cells, and intestinal intraepithelial γ δ T cells are absent in these mice. Normal numbers of bone marrow HPCs and a similar capability of these marrow cells to generate myeloid and erythroid colonies as wild-type mice indicates that specific defects in lymphoid progenitor cells exist. Thymic progenitors are severely deficient. This phenotype is attributable to failure of IL-7 and IL-2 signaling, which explains the T-cell deficiency; the absence of NK cell development has been attributed to an impairment in IL-15 signaling. There is a high apoptotic rate in the lymphocytes generated in these mice, and this is consistent with the identified function of JAK3 in regulating Bcl-2 and Bax.

Activation of JAK3 caused by gain-of-function mutations is found in several human hematologic malignancies, including acute megakaryoblastic leukemia and cutaneous T-cell lymphoma.

Given the essential role of JAK3 in cytokine signaling through γc and given its limited tissue expression, inhibition of JAK3 activity has emerged as a promising strategy for immunosuppression for autoimmune disorders and immune rejection.

Tyrosine Kinase 2

Tyrosine kinase 2 was the first JAK family member identified in cytokine signaling.Tyk2 was discovered as an essential component in a screen for mutants in IFN-α signaling. Type I IFN receptors require Tyk2 and JAK1, but IFN-γ signaling depends on the combination of Tyk2 and JAK2.[17] The combination of Tyk2 with JAK2 is not only required for IFN-γ signaling but also for the differentiation of IFN-γ–producing Th1 cells from naive Th cells. Lymphocyte development and proliferation are not affected in Tyk2-deficient mice, but

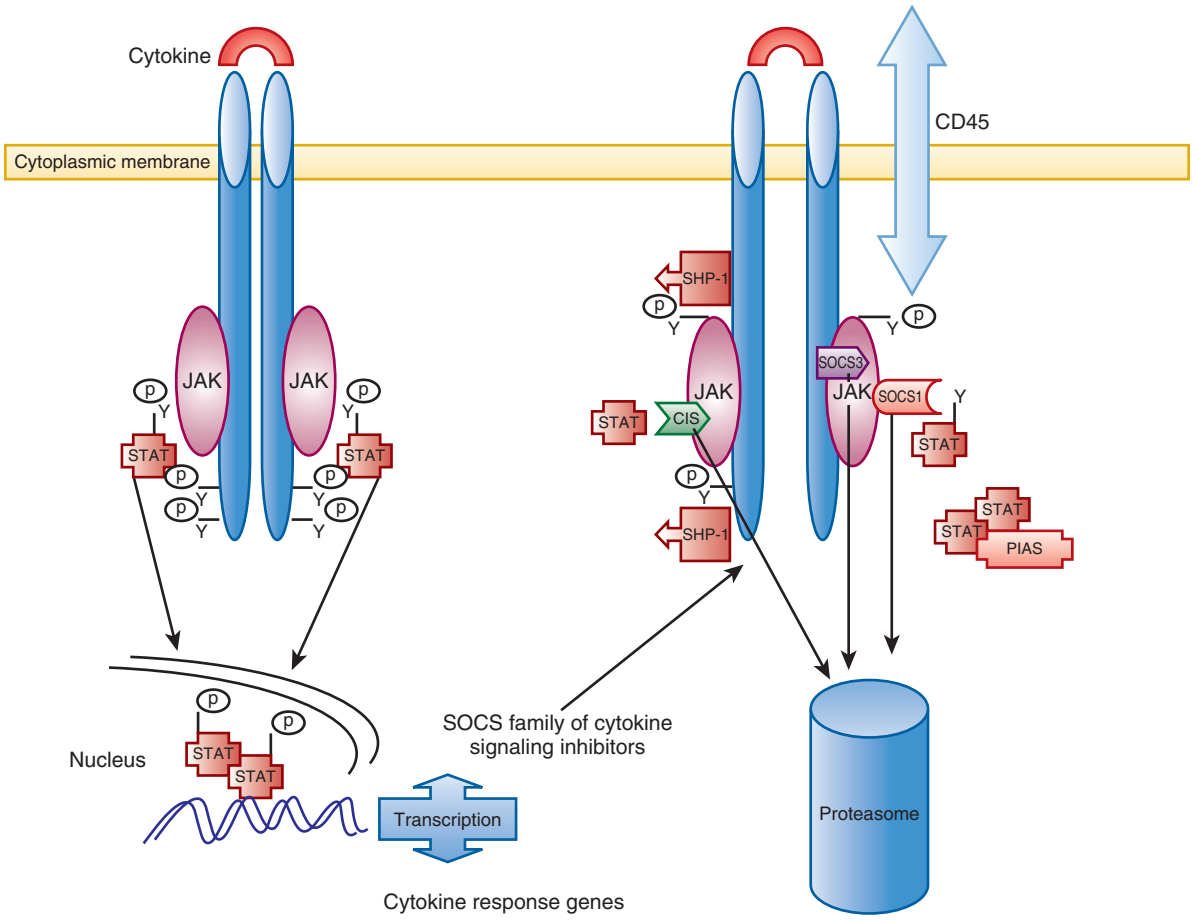

Figure 14-3 CYTOKINE–RECEPTOR INTERACTIONS. A general depiction of signal transduction by cytokine receptor superfamily. Ligand binding leads to dimerization or oligomerization of the receptor, which brings into proximity the associated Janus kinases (JAKs). The Latter phosphorylate tyrosine residues on the receptor and JAKs. This phosphorylation creates docking sites for proteins containing Src homology (SH2) domains such as signal transducers and activators of transcription (STATs). These hetero- or homodimerize and translocate to the nucleus, where they affect transcription of target genes. Several mechanisms exist to reverse this cytokine-activated state. STATs trigger a negative feedback loop by inducing transcription of suppressors of cytokine (SOCSs). There are eight SOCS members. SOCS1 interacts directly with JAK1 and inhibits its catalytic activity. Cytokine-inducible SH2-domain-containing proteins (CIS), another SOCS, binds the receptor and blocks binding and phosphorylation of STATs. SOCS3 binds the receptor before inhibiting JAK. SOCS proteins contain a SOCS box that leads to proteosomal degradation of the SOCS-associated molecules. Src-homology 2 containing phosphatase 1 (SHP1) is a tyrosine phosphatase that negatively regulates the cytokine transduction process by dephosphorylating JAKs and the cytokine receptors. CD45 is a transmembrane phosphatase that inactivates JAKSs. Protein inhibitors of activated STAT (PIAS) family members interact with STAT dimers and inhibit their functions as described in the main text.

signaling by cytokines that are important for host defense is impaired.[18] The IL-12 receptor (IL-12R) is associated with Tyk2 and JAK2 and activates mainly the transcription factor STAT4. IL-12 signaling is strongly impaired in the absence of Tyk2, and downstream activation of STAT3 and STAT4 is clearly reduced, resulting in the inability of IFN-γ production by T cells. Both STAT3 and STAT1 activation by type I and type II IFNs is reduced in Tyk2-deficient mice, although at high concentration, IFN-α can fully transduce its signal in the absence of Tyk2. IL-10 signaling is essentially normal. Because of all of the above, Tyk2-deficient mice are susceptible to viral and bacterial infections. This susceptibility can be explained by impaired Th1 lineage development, but Th17 differentiation also seems to be affected in the absence of Tyk2. Because IL-4 is essential in generating Th2 cells and because its signaling is independent of Tyk2, there is no disruption of Th2 in Tyk2-deficient mice. Th2 cell differentiation can also be inhibited by Tyk2-mediated signals derived from IL-12 or IFNs. As expected, Th2-induced diseases such as allergic bronchitis are enhanced in the background of Tyk2 deficiency. One example is a mouse asthma model in which pronounced lung inflammation is noted because of an enhanced Th2 response with an increase of IL-4 production, increased IgE levels, and recruitment of eosinophils.[19]

Signal Transducers and Activators of Transcription

There are seven STAT family members that share a similar structure, but mediate distinct biologic functions.[20] Fig. 14-6 shows the general structure of a STAT. STAT1, for example, harbors an *N*-terminal domain followed by an α-helical coiled-coil and a DNA-binding domain and a linker that connects to the C terminus. The C terminus contains an SH2 domain followed by a short region containing a tyrosine residue, which is critical for the activation by JAK-mediated phosphorylation, and a transactivation domain, which is the most divergent part within the STAT family. STAT proteins can be tyrosine phosphorylated by receptor-associated JKs, by growth factor receptor Tyks, or by nonreceptor Tyks. Latent STATs diffuse freely in the cytoplasm. Upon STAT phosphorylation and

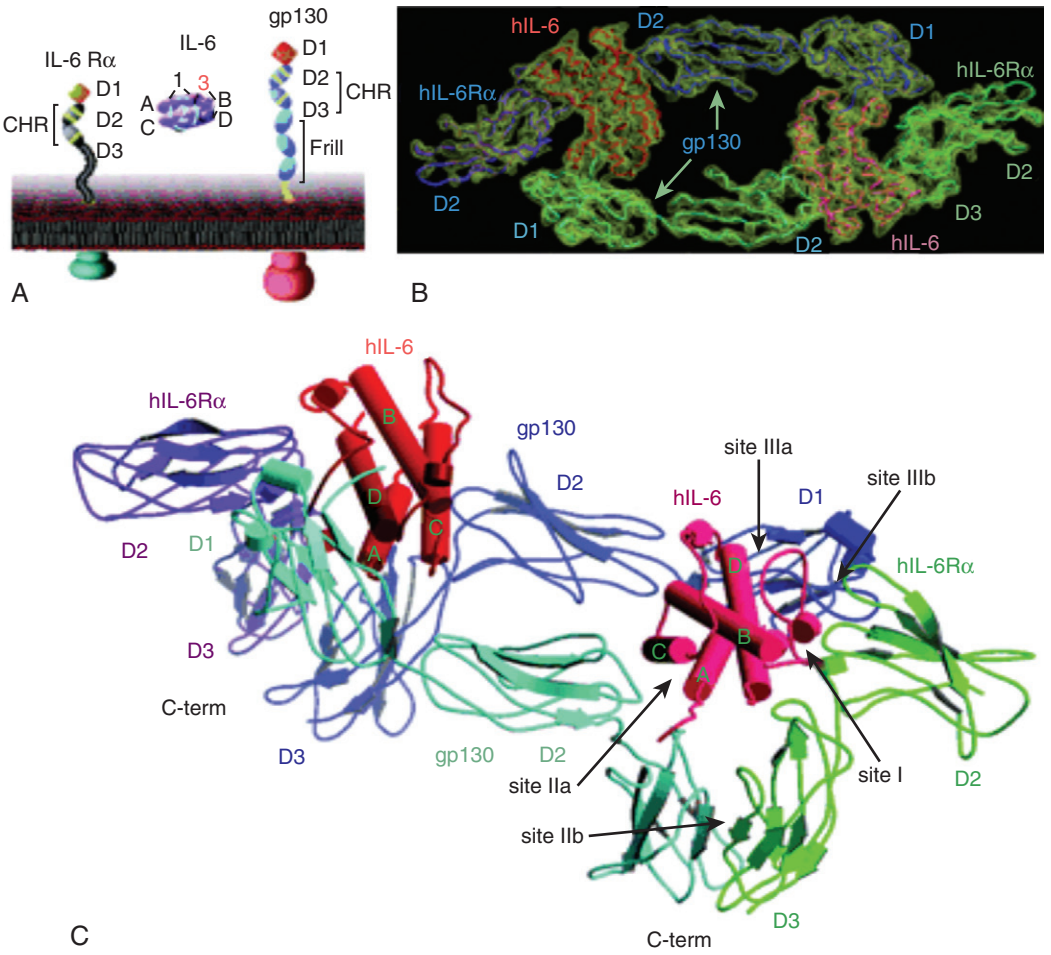

Figure 14-4 INTERLEUKIN-6 (IL-6) COMPLEX STRUCTURE. **A,** The complex is a hexamer consisting of interleukin-6 (IL-6), the IL-6 α-receptor (IL-6Rα), and the shared signaling receptor gp130. **B,** The 3.65 angstrom–resolution shows a hexameric, interlocking assembly mediated by a total of 10 symmetry-related, thermodynamically coupled interfaces. Assembly of the hexameric complex occurs sequentially: IL-6 is first engaged by IL-6Rα and then presented to gp130 to activate the downstream signaling. **C,** The domain structure of IL-6 engaging its receptor complex. *(Adapted from Boulanger MJ, Chow DC, Brevnova EE, et al: Hexameric structure and assembly of the interleukin-6/IL-6 alpha-receptor/gp130 complex.* Science *300:2101, 2003.)*

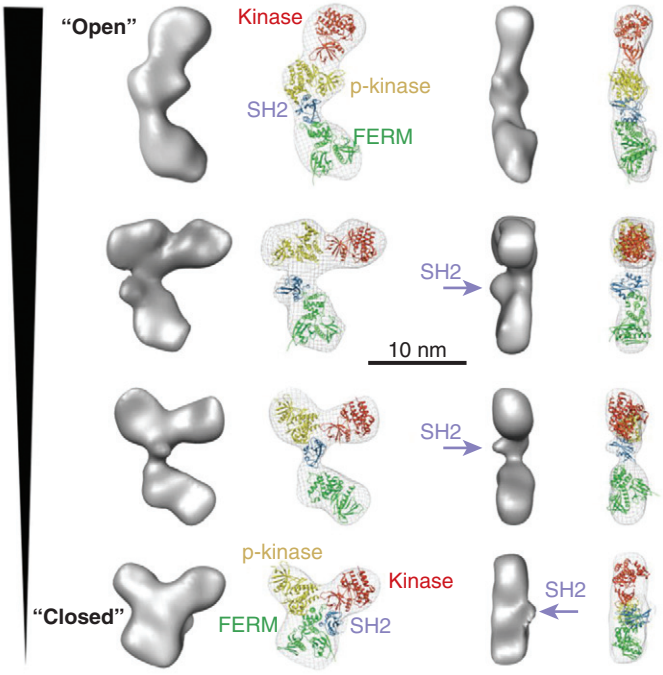

Figure 14-5 3D REPRESENTATION OF JAK1 SHOWING IT FORMING THREE LOBES. It switched *in vitro* from an open to a closed conformation. The orientations of the reconstructions in the left column represent the particles face-on, while the orientations to the right are rotated 90°, reflecting the flatness of the surface on which Jak1 is lying. It is uncertain whether the open or the closed conformation represents the active state. *FERM,* 4.1, ezrin, radixin, moesin; *SH2,* Src homology. *(Adapted from Lupardus PJ, Skiniotis G, Rice AJ, et al: Structural snapshots of full-length Jak1, a ransmembrane gp130/IL-6/IL-6Rα cytokine receptor complex, and the receptor-Jak1 holocomplex.* Structure *19:45, 2011.)*

dimerization with a partner, the dimer quickly translocates to the nucleus (Fig. 14-7). This is done through an active process mediated by the nuclear transport machinery. For example, phosphorylated STAT1 transport is facilitated by the importin-α5/importin-β1 heterodimer. This nuclear movement culminates in DNA binding and transcriptional activity. For example, IFN-γ binding to its receptor leads to tyrosine phosphorylation of STAT1. The STAT1 dimer was originally called the *IFN-γ activated factor* (GAF). It recognizes a DNA sequence termed the *IFN-γ activated sequence* (GAS), which contains an inverted repeat of GAAA residues spaced by two to four nucleotides. Below we will briefly discuss the biologic activities of STAT proteins largely inferred from gene targeting experiments.

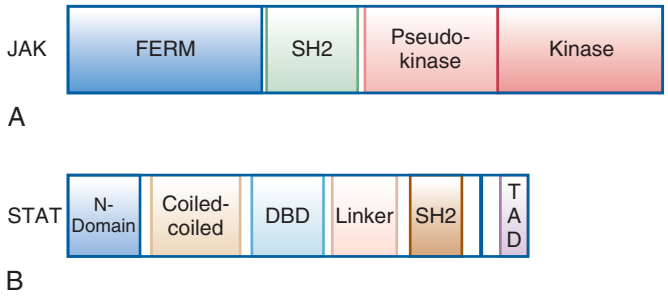

Figure 14-6 GENERAL STRUCTURE OF JANKUS KINASE (JAK) AND STAT PROTEINS. **A,** JAK protein consists of the 4.1, ezrin, radixin, moesin (FERM) domain (which modulates the kinase activity), Src homology (SH2) domain for phospho-tyrosine binding, pseudokinase (which can exert inhibitory function), and kinase domain. **B,** STAT protein consists of an N-terminus domain, coiled-coiled domain for protein interaction, DNA binding domain (DBD), linker domain, SH2 domain, conserved tyrosine, and transactivation domain (TAD), which binds transcription regulators.

Signal Transducer and Activator of Transcription 1

STAT1 mediates signaling from IFNs. STAT1-deficient mice show no significant developmental abnormalities, but they display a complete lack of responsiveness to either IFN-α or IFN-γ and are highly sensitive to infection by microbial pathogens and viruses.[21] The induction of IFN-inducible genes is disrupted. A missense mutation of STAT1 was initially identified in a patient with atypical mycobacterial infections, similar to individuals with mutations of IFNγR subunits. However, this STAT1 mutation was not associated with susceptibility to viral infections.[22] Since then, other families have been described with mutations in STAT1 that lead to viral and mycobacterial infections. Recently, families with mucocutaneous candidiasis have been reported with STAT1 mutations.[23] These families have defective Th1 and Th17 responses. Not all IFN-dependent signaling is regulated by STAT1 because there is a large number of STAT1-independent genes that are induced by IFN-γ, and this may explain the observations that STAT1$^{-/-}$ mice are less susceptible to infection

Table 14-1 Consequence of Deficiencies in Genes Encoding Intracellular Signaling Molecules*

Signal Transduction Molecule	Phenotype of Deficient Mice
JAK1	Perinatal mortality, defects in IL-6, IL-2, and cytokine receptor type II families
JAK2	Embryonic lethality caused by defective definitive hematopoiesis; defects in EPO, TPO, IL-2 family, IL-3, and IFN-γ signaling
JAK3	Immunodeficiency caused by absent common γ chain signaling; JAK3 expression is restricted to the hematopoietic system
TYK2	Reduced responses to IFN-α/β, IL-12, and IFNγ
STAT1	Complete lack of responsiveness to either IFN-α/β or IFN-γ and high sensitivity to infections by viruses and other microbial pathogens; normal response to other cytokines such as GH and IL-10
STAT2	Lack of responsiveness to IFN-α/β; susceptibility to viral infections
STAT3	Early embryonic lethality before gastrulation
	STAT3 $^{-}$/+ mice demonstrate decreased HSC/HPCs
STAT4	Defective Th1 and Th17 responses caused by defective IL-12, IL23 signaling
STAT5a	Defective mammary gland development and lactogenesis; GM-CSF and FL signaling is impaired but no gross hematopoietic abnormalities
STAT5b	Disrupted sexual dimorphism of body growth rates; defective GH signaling
STAT5a/b	Anemic embryos of the double knock-outs with apoptotic erythroid progenitors caused by impaired EPO signaling; adult mouse erythrocyte RBC number is normal; loss of GH and prolactin signaling; infertile females; severe impairment of IL-2–induced T-cell responses
STAT6	Defective Th2 response with defective IL-4 signaling
SHP-1	Natural mutation in *moth-eaten* mice results in hair loss, immunodeficiency, autoimmune disorders, enhanced SDF-1 chemotactic activities, and enhanced hematopoietic progenitor proliferation in response to cytokines such as GM-CSF
CD45	Enhanced cytokine and IFN-receptor–mediated activation of JAKs and STATs
SOCS1	Neonatal lethality probably caused by excessive IFN-γ responses, with hematopoietic infiltration of multiple organs, lymphopenia, and fatty liver degeneration
SOCS2	Gigantism caused by GH or IGF-1 excessive signaling
SOCS3	Embryonic lethality with placental defect; erythrocytosis in embryos

EGF, Epidermal growth factor; *EPO*, erythropoietin; *FL*, Flt-Ligand; *GH*, growth hormone; *GM-CSF*, granulocyte macrophage colony-stimulating factor; *HPC*, hematopoietic progenitor cell; *HSC*, hematopoietic stem cell; *IFN*, interferon; *IGF-1*, insulin-like growth factor-1; *IL*, interleukin; *JAK*, Janus kinase; *RBC*, red blood cell; *SDF-1*, stromal derived factor-1; *SHP*, Src homology 2 containing phosphatase; *SOC*, suppressor of cytokine signaling; *STAT*, signal transducer and activator of transcription.
*This table outlines the phenotypes of mice deficient in the major signaling molecules that directly interact with the cytokine receptors. The phenotypes range from significant embryonic lethality caused by hematopoietic impairment to less remarkable defects in other organ systems. Please refer to the main text for more details on the functions of these molecules.

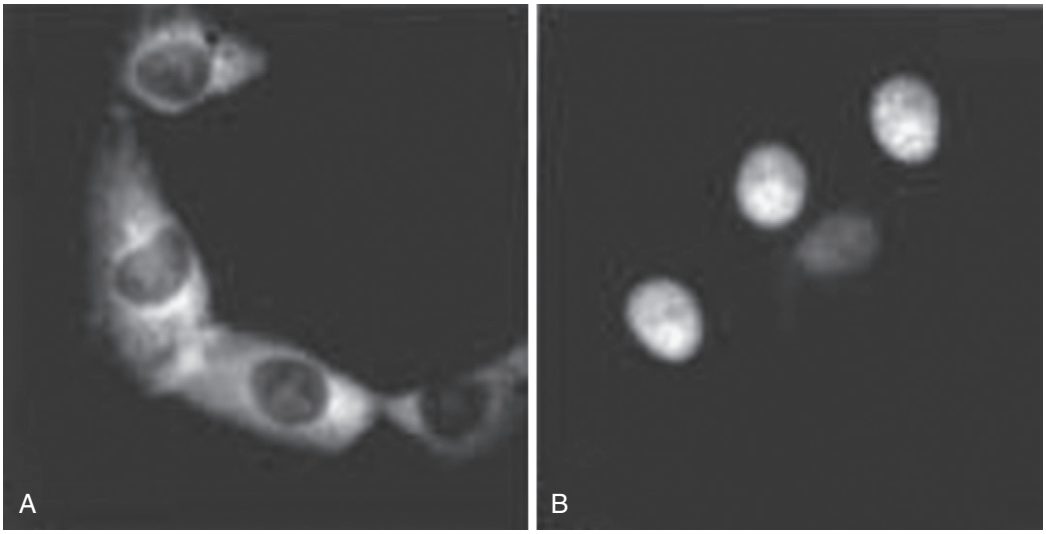

Figure 14-7 DEMONSTRATION OF STAT PROTEIN LOCATION RESPONSE TO CYTOKINE SIGNALING. U3A cells expressing STAT-Green Fluorescent Protein (STAT-GFP) were untreated **(A)** or treated **(B)** with interferon-γ for 30 min. One can observe the migration of STAT1 from the cytoplasm to the nucleus. *(Adapted from McBride KM, McDonald C, Reich NC: Nuclear export signal located within the DNA-binding domain of the STAT1 transcription factor.* EMBO J *19:6196, 2000.)*

than mice lacking both IFN-γ and IFN-α/β receptors. Other less pronounced defects have been described in STAT1-deficient mice such as a subtle decrease in bone marrow erythroid progenitors. STAT1 regulates other cytokine/growth factor signaling. One example is its role in the inhibitory activity of fibroblast growth factor on chondrocytes mediated by transcriptional activation of cell cycle inhibitors. Another example of IFN-independent activity of STAT1 is the regulation of NK cells whose function is more severely impaired by STAT1 deficiency than by deficiencies of both IFN-γ and IFN-α/β receptors.

Because IFNs have antineoplastic activities, a role for STAT1 in tumor suppression was suspected, and indeed, STAT1-deficient mice have higher incidence of tumor formation in response to chemical carcinogens and also on a background of P53 deletion. However, given the involvement of STAT1 in other cellular pathways such as myc regulation and apoptosis, it cannot be concluded with certainty that this tumor-promoting phenotype is completely caused by a lack of immune surveillance.

Signal Transducer and Activator of Transcription 2

The main function of STAT2 is to mediate IFN-α/β signaling. STAT2 is constitutively associated with a non-STAT protein, IFN regulatory factor 9 (IRF-9). Tyrosine phosphorylated STAT1–STAT2–IRF-9 multimeric complex is called the IFN-stimulated gene factor 3 (ISGF3). This complex binds to a specific DNA sequence in type I IFN-induced genes called the IFN-stimulated response element (ISRE). Because of the impaired IFN-α/β responsiveness, STAT2 knockout mice are susceptible to viral infections.[24] As is the case with STAT1-deficient mice, STAT2-deficient mice are viable and develop normally. The absence of STAT2 results in reduced tyrosine phosphorylation and activation of STAT1 because STAT2 facilitates recruitment and activation of STAT1 by the IFN-α/β receptor complex.

Signal Transducer and Activator of Transcription 3

STAT3 mediates signaling from multiple cytokines. It was originally cloned as an acute-phase response factor activated by IL-6. Murine embryos deficient in STAT3 die at postcoital day 7.5. One potential explanation for this early embryonic death is failure of extraembryonic trophoblast caused by impaired leukemia inhibitory factor signaling. Cell line–specific conditional STAT3 deletions have been reported for multiple lineages with no major developmental abnormalities.[25] STAT3-deficient T cells and hepatocytes have poor responses to IL-6. Deletion of STAT3 in macrophages results in constitutively activated cells and increased sensitivity to lipopolysaccharide. This is attributed to the role for STAT3 in the antiinflammatory responses induced by IL-10. $CD4^+$ T cells can differentiate into the Th17 cells whose development and function are critically dependent on STAT3. These cells produce the inflammatory cytokine IL-17 and are responsible for recruitment and activation of neutrophils and other inflammatory cells. Th17 cells can be generated from naive $CD4^+$ T cells by IL-6 and TGF-β but can also produce another cytokine IL-21, which promotes IL-17 production in an autocrine–paracrine manner. Another cytokine, IL-23, also acts to expand and maintain Th17 cells. The importance of IL-23 signaling in inflammation is exemplified by recent discoveries that polymorphisms in *IL23R* are associated with an increased risk of developing inflammatory bowel disease, ankylosing spondylitis, and psoriasis. IL-6, IL-21, and IL-23 all activate STAT3 by binding to their cognate receptors. The importance of STAT3 in Th17 cell development and function is appreciated in patients with Job syndrome, an autosomal dominant disorder caused by STAT3 mutations, which is associated with a failure to make Th17 cells.

STAT3 deficiency in multiple types of T cells results in decreased IL-21 production, which is required for hematopoietic progenitor proliferation. STAT3 promotes optimal Th2 cell differentiation and cytokine production in the presence of activated STAT6.

Selective targeting of the STAT3b isoform has been reported, and these mice exhibit diminished recovery from endotoxic shock. STAT3 deletions in other cell lineages have been described. For example, STAT3 deletion in mammary glands result in a delay in involution after weaning because of a decrease in apoptosis. STAT3-deficient epidermal cells show defective wound healing and in vitro migration of epidermal cells.

STAT3 is activated in multiple tumor types. This activation enhances tumor cell survival mediated by multiple mechanisms, including enhanced levels of prosurvival genes (e.g., Bcl-2 and Bcl-X_L). STAT3 is also frequently activated in cells that are transformed by a variety of oncogenes (e.g., v-src and BCR-abl). The enforced expression of a constitutively active STAT3 homodimer is sufficient to transform immortalized fibroblasts. STAT3 inhibitors are in early clinical trials for advanced malignancies.

Signal Transducer and Activator of Transcription 4

STAT4 is predominantly activated in response to IL-12, which drives T-helper cell differentiation into the Th1 and Th17 pathways. The phenotype of STAT4 deficient mice is very similar to that of mice lacking IL-12. IL-12 promotes differentiation of naive $CD4^+$ T cells to Th1 cells, which produce IFN-γ and augment cell-mediated immune responses. Th1 cells are critical in host defense against intracellular pathogens and tumors and in the pathogenesis of autoimmune diseases. Thus, the phenotype of STAT4-deficient mice includes impaired Th1 differentiation, IFN-γ production, and cell-mediated immunity.[26] IL-12–, IL-12 receptor–, and STAT4-deficient mice have increased susceptibility to infection with intracellular organisms. STAT4-deficient mice are resistant to autoimmune diseases characterized by a Th1 response. A common single nucleotide polymorphism of the STAT4 gene has been shown to be associated with susceptibility to rheumatoid arthritis, systemic lupus erythematosus, and primary Sjögren syndrome.[27] In acute sepsis, whereas STAT4 deficiency is associated with improved survival, $STAT4^{-/-}$ mice had *increased* lethality in a noninfectious sepsis model. It appears that STAT4 may have either pro- or antiinflammatory effects, depending on the context.

STAT4 is also activated by IL-23. Additionally, in humans but not in mice, IFN-α/β induces STAT4 phosphorylation. This is notable because IFN-α/β can promote Th1 differentiation in humans and not in mice. This has been explained by the finding that the STAT4/STAT2 dimer is recruited to the human type I IFN receptor via the carboxy terminus of STAT2. STAT4 also mediates IFN-γ production by DCs and macrophages induced by IL-12, and this may explain the mechanisms by which DCs promote Th1 differentiation.

Signal Transducer and Activator of Transcription 6

STAT6 is primarily activated by IL-4 and IL-13. STAT6-deficient mice lack most of the physiologic functions associated with IL-4. In particular, the ability of IL-4 to induce the in vitro differentiation of Th2 cells is lost.[26] STAT6 is critically involved in several distinct aspects of allergic inflammatory disease, such as airway hyperresponsiveness, eosinophilic infiltration, and responses of mast cells. B cells of STAT6-deficient mice cannot undergo class switching to produce IgE against helminthes and allergens. As expected, $STAT6^{-/-}$ mice have impaired expulsion of helminthic parasites and reduced pathology in models of asthma. $STAT6^{-/-}$ mice have increased lethality, inflammation, and cytokine production in a noninfectious model of endotoxemia but reduced lethality and enhanced clearance of bacteria in an infectious model.

STAT6 induces expression of GATA3, which is considered a Th2 cell master regulator. Transgenic mice expressing IL-4 or constitutively active STAT6 are characterized by the development of spontaneous allergic inflammation. Certain chemokines such as CCL11, CCL17, CCL22, and CCL26 have been reported to be regulated in a STAT6-dependent manner and are involved in allergic disorders. Although a number of pathways, including the mitogen-activated protein kinase (MAPK) and the phosphoinositide-3-kinase (PI-3-K), are involved in the signal transduction of IL-4, IL-4-induced T-cell differentiation appears to occur almost exclusively via STAT6. IL-4 also antagonizes Th1 responses through STAT6. In fact, residual STAT4-independent Th1 differentiation becomes apparent in doubly deficient STAT4/STAT6 knockout mice. A study on murine mast cells demonstrated IL-15-inducible STAT6 phosphorylation, involving Tyk2, although IL-15 was less potent than IL-4.

Signal Transducer and Activator of Transcription 5

The genes encoding STAT5A and STAT5B are juxtaposed, and the transcriptional start sites are within 10 kb of each other. Although the *STAT5a* and *STAT5b* gene promoters might share certain regulatory elements, lineage-specific expression has been reported. The highly related STAT5 proteins (a and b) are activated in response to a variety of cytokines and Tyk receptors. Mice lacking STAT5a, STATb, and STAT5a/b display distinct phenotypes, suggesting discrete functions for these proteins. STAT5a deficiency results in the loss of prolactin-dependent mammary gland development, which is necessary for lactation. STAT5b-deficient mice are sexually dimorphic with growth retardation. In contrast, a good portion of STAT5a/b double knockout mice die within a few weeks of birth, and these mice are infertile with defective corpus luteum development, and have defective mammary gland development. Both male and female STAT5a/b-deficient mice are small with small fat pads and reduced levels of insulinlike growth factor-1 (IGF-1). STAT5a/b double knockout mice have hypocellular bone marrows, lymphopenia, neutrophilia, and modest anemia and thrombocytopenia.[28] Moreover, the hematopoietic progenitors of STAT5a/b-deficient have defective bone marrow repopulating capacity. Myeloid development is grossly normal in STAT5a/b knockout mice, but in vitro cytokine-dependent proliferation, survival, and migration of myeloid cells are impaired. With respect to T- and B-cell development, complete deletion of the STAT5a/b locus results in severely impaired lymphoid development and differentiation with abrogated T-cell receptor γ rearrangement and survival of peripheral $CD8^+$ T. In other words, complete STAT5 deficiency results in SCID, similar in lymphoid phenotype to deficiencies of IL-7R, γc, and JAK3. Whereas deficiency of both STAT5a and STAT5b results in loss of $CD4^+$ regulatory T (Treg) cells, which express the transcription factor Foxp3, constitutive activation of STAT5b enforces Foxp3-positive Treg-cell development, bypassing the requirements for upstream cytokine or costimulatory signals to activate foxp3 transcription. STAT5 deficiency abrogates transformation by Tel-JAK but not by v-Abl or BCR-abl. Mutations in the *STAT5B* gene in a few patients with severe growth retardation have been described. Loss of functional STAT5B is associated with severe IGF-1 deficiency, indicating that this pathway is responsible for most of the GH-induced IGF-1 production.

NEGATIVE REGULATORS OF CYTOKINE SIGNALING

Src-Homology 2 Containing Phosphatase 1

SHP1 is a cytoplasmic phosphotyrosine phosphatase whose expression is limited to the hematopoietic system. SHP1 was identified as the protein encoded by the mutated locus *(Hcph)* in *moth-eaten (me)* mice.[29] These mice display severe immunologic dysfunction, particularly enhanced proliferation of macrophages and neutrophils in the lungs, which leads to pneumonitis, and in the skin, which causes patchy dermatitis that results in the "moth-eaten" phenotype. SHP1 associates with cytokine receptors and dephosphorylates JAK kinases. For example, it downregulates EPO-induced signaling by binding to the EPOR and dephosphorylating JAK2 associated with the EPOR. SHP1 also dephosphorylates JAK1 because IFN-α–induced phosphorylation of JAK1 is enhanced in SHP1 deficient macrophages. SHP1 also interacts with JAK3. This interaction may explain the activation of JAK3/STAT3 pathway in some cases of ALK (+) anaplastic large cell lymphoma in which SHP1 appears to be suppressed by promoter methylation. The expression of an inactive SHP1 in the cytokine-dependent cell line Ba/F3 increased the proliferative response to IL-3, STAT5 phosphorylation, and cell survival after IL-3 withdrawal.

Consistent with a negative role of SHP1 in the JAK–STAT pathway, silencing of SHP1 by promoter methylation is often associated with various kinds of leukemias, lymphomas, and myeloma, and the effect caused by SHP1 silencing is at least partially attributed to increased activities in the JAK–STAT pathway. On the other hand, in a limited number of cases, SHP1 was described to have a positive role in promoting JAK/STAT signaling. For example, the epidermal growth factor, and IFN-γ–induced STAT activation was suppressed by expressing a catalytically inactive form of SHP1 in HeLa cells, but

this pathway was essentially unaffected by the expression of WT SHP1. There is no molecular explanation described for this observation.

Src-Homology 2 Containing Phosphatase 2

SHP2 is a protein–tyrosine phosphatase that is widely expressed, with high level expression in hematopoietic cells. It contains 2 tandem Src homology 2 (SH2) domains (N-SH2 and C-SH2), a protein tyrosine phosphatase (PTP) domain, and a C-terminal tail. SHP2 has low basal enzymatic activity because of autoinhibition of the PTP domain by the N-SH2 domain. SHP2 directly or indirectly (via adaptor proteins) associates with activated receptor protein Tyks or cytokine receptors via its two SH2 domains. Binding of SH2 domains to phosphotyrosine sites of these receptors alters the conformation of the N-SH2 domain, releasing its binding to PTP domain and causing catalytic activation. Despite being a phosphatase, SHP2 promotes activation of the Ras and ERK pathway by cytokines. Its catalytic activity is required for cytokine activation of the phosphatidylinositol 3–kinase pathway. SHP2 plays an essential role in hematopoietic cell development. Embryonic lethality is observed at day 8.5 in mice with a truncated version of SHP2 because of severe defects in gastrulation and mesodermal patterning.[30] Complete loss of SHP2 causes embryonic death in the peri-implantation period, and SHP2 is required for trophoblast stem cell survival. Hematopoietic stem cells (HSCs) from SHP2 haploinsufficient mice display a competitive repopulating defect. Embryonic stem (ES) cells lacking SHP2 exhibit severely decreased differentiation to erythroid and myeloid progenitors in vitro and fail to contribute to erythroid and myeloid lineages in chimeric mice derived from $SHP2^{-/-}$ ES cells and wild-type embryos. SHP2 loss of function causes an early block of lymphocyte development before pro-T and pro-B stages. The exact mechanisms through which SHP2 regulates cytokine signaling and hematopoiesis are uncertain. SHP2 both enhances and inhibits signaling in the JAK–STAT pathway depending on the context. It was shown, for example, to dephosphorylate STAT1 and STAT5. At the same time, SHP1 is required for optimal JAK2 activation.

Activating germline mutations of *PTPN11* (the gene encoding for SHP2 protein) are seen in persons with Noonan syndrome, and loss-of-function mutations are seen in LEOPARD (lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retarded growth, and deafness: sensorineural) syndrome. Both are congenital disorders associated with abnormal hematopoiesis. Somatic activating mutations are seen in approximately 35% of juvenile patients with myelomonocytic leukemia. PTPN11 mutations are also seen in patients with myelodysplastic syndrome, acute lymphoblastic leukemia, and acute myelogenous leukemia. These gain-of-function mutations induce hyperactivation of the Ras pathway, which results in growth factor– and cytokine-independent proliferation and survival of hematopoietic progenitor cells (HPCs). Increased SHP2 expression has also been observed in acute leukemia specimens, suggesting a potential role in leukemogenesis.

CD45, PTP1B, TC-PTP, PTPRT, and PTP-BL

CD45 is a receptor-like tyrosine phosphatase highly expressed by hematopoietic cells. CD45 was identified as a JAK family phosphatase.[31] CD45 is able to dephosphorylate all JAKs in murine cells and dephosphorylate JAK1 and JAK3 in human cells.[32] Targeted disruption of the CD45 gene leads to enhanced cytokine and IFN receptor–mediated activation of JAK and STAT proteins. The removal of CD45 also increased erythroid colony formation and antiviral activity, which is consistent with the fact that CD45 negatively regulates EPO and IFN signaling. The Src family kinase members Lck and Lyn are key substrates for CD45 in T and B lymphocytes, respectively. CD45 lowers the threshold of antigen receptor signaling, which impacts T- and B-cell activation and development.

Protein tyrosine phosphatase 1B (PTP1B) and T-cell PTP (TC-PTP) are closely related PTPs, sharing 74% homology in their catalytic domain.[33] Although PTP1B is expressed in many tissues, TC-PTP (gene name, *PTPN2*) is ubiquitously expressed with particularly high expression in hematopoietic tissues. PTP1B is involved in multiple signaling pathways by downregulating several Tyks. For example, PTP1B-deficient mice display attenuated insulin signaling. Increased phosphorylation of JAK2, Tyk2, STAT3, and STAT5 has been observed in PTP1B-deficient embryonic fibroblasts. TC-PTP targets multiple STAT and JAK proteins in addition to growth factor receptors for dephosphorylation. TC-PTP–deficient mice develop anemia, lymphadenopathy, and splenomegaly and die at an early age. These mice display excessive inflammation but demonstrate increased number of BM HSCs and HPCs. Other phosphatases, such as PTP-receptor type T (PTPRT) and PTP-basophil like (PTP-BL), have also been implicated in cytokine signaling but will not be discussed here further.

Protein Inhibitor of Activated STAT

Protein inhibitor of activated STAT3 (PIAS3) was the first family member to be identified as a repressor of STAT3 activity. Three additional family members PIAS1, PIASy (or PIAS4), and PIASx (or PIAS2) were later identified with high-sequence homology. Other proteins with weak homology (hZIMP7 and hZIMP10) have been reported. PIAS1 was identified as a STAT1-interacting protein and subsequently found to inhibit STAT1-mediated transcriptional activation. The PIAS family members PIASx and PIASy were identified based on sequence similarity to PIAS1 and have been shown to inhibit STAT1 and STAT4, respectively. PIAS proteins have been shown to impact on the function of many different proteins, with particular involvement in gene transcription.

PIAS proteins contain a domain known as Siz/PIAS-RING (SP-RING) with structural similarity to ubiquitin E3 ligase RING fingers (Fig. 14-8). It was shown that PIAS binds the protein modifier small ubiquitin-like modifier (SUMO)[34] and recruits the E2 SUMO ligase UBC9, which transfers SUMO to target proteins, particularly to transcription factors such as STATs. PIAS1, PIAS3, and PIASx all sumoylate STAT1 at Lys-703 close to the site at which it is phosphorylated by JAKs (Tyr-701), and mutation of Lys-703 results in an increased response to IFN-γ (IFN-γ).

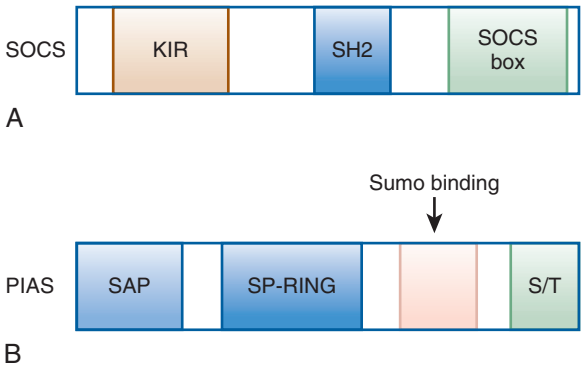

Figure 14-8 THE GENERAL STRUCTURE OF A SUPPRESSOR OF CYTOKINE SIGNALING (SOCS) AND A PROTEIN INHIBITORS OF ACTIVATED STAT (PIAS) PROTEIN. **A,** SOCS protein has a central Src homology (SH2) domain; an amino-terminal domain of variable length; and divergent sequence, which contains a kinase inhibitory region (KIR) and a carboxy-terminal 40-amino-acid SOCS box. **B,** PIAS protein contains a SAP (SAFA/B, ACINUS, PIAS) domain that is present in other chromatin-associated proteins. PIAS proteins which are Small Ubiquitin-like MOdifier (SUMO) E3 ligases contain a conserved SP-RING domain that shares sequence similarity to RING domains of ubiquitin E3 ligases. This domain recruits the SUMO E2 ligase (UBC9).

Thus, the binding of PIAS to STAT results in the inhibition of STAT-mediated gene activation. PIAS1 and PIAS3 inhibit STAT DNA binding activity, and PIASy and PIASx repress STAT1 and STAT4-mediated gene activation without affecting DNA binding. PIAS proteins also act by recruiting other corepressor molecules. One example is the inhibition of natural regulatory T-cell differentiation by PIAS1 through chromatin–based epigenetic repression.[35] Sumoylation may impact nuclear localization of proteins because it is the case for the transcriptional factor LEF1, where LEF1 sumoylation by PIASy results in its sequestration into nuclear bodies hindering its transcriptional activity. Given its impact on STAT1 and by that on IFN signaling, PIAS1 has a tangible role in innate immunity. The antiviral activity of IFNs is significantly increased in PIAS1–/– cells.[36] In addition, PIAS1–/– mice show increased protection against bacterial and viral infection.

Suppressor of Cytokine Signaling

The suppressor of cytokine signaling (SOCS) family consists of eight proteins that antagonize the signaling of STAT proteins. STATs activate the transcription of genes encoding the SOCS family as a negative feedback regulation.[37] For example, expression of SOCS3 is activated by several transcription factors, including STAT1, STAT3, and MAPK p38, but expression of SOCS1 is dependent on the production of IRF-1, a STAT1-inducible transcription factor. Each SOCS has two major domains, an SH2 domain and a Socs box, which mediates a complex formation with elongins B and C, a cullin, and Rbx2, to form E3 ubiquitin ligase (see Fig. 14-8). SOCS proteins function in a negative feedback loop to inhibit cytokine signaling by binding to either phospho-JAK or phospho-receptor through SH2 domain, and this inhibits JAK activity directly or by targeting the receptor complex for ubiquitylation and subsequent proteasome-mediated degradation. Gene-targeting studies have delineated the distinct in vivo functions of SOCS proteins. For example, SOCS1 –/– mice die as neonates from an inflammatory disease caused by dysregulated IFN signaling and which presents as lymphopenia, infiltration of macrophages and T cells into the liver and other organs, and fatty degeneration of the liver.[22] A SOCS3 deletion results in embryonic lethality at 12 to 16 days associated with marked erythrocytosis.[38] In addition, the in vitro proliferative capacity of high-proliferative potential progenitor cells is greatly increased.

FUTURE DIRECTIONS

A short review of cytokine signaling from a historical perspective has been published.[39] The past 4 decades have witnessed significant progress in our understanding of cytokines and their diverse functions, starting with cloning cytokines, identifying their receptors, cloning the receptors, and elucidating the complex signaling pathways triggered by ligand–receptor engagement. This has reflected positively on human health, particularly in the field of hematology and immunology, where the pathogenesis of multiple disorders has been uncovered and connected to defective cytokine signaling. We are witnessing, as a result, a plethora of targeted therapies that aim at abnormal cytokine signaling as a strategy to reverse morbid phenotypes.

CHAPTER 15

CONTROL OF CELL DIVISION

William M.F. Lee and Chi V. Dang

Somatic cells undergo one of several general fates: They proliferate by mitotic cell division, differentiate and acquire specialized functions, and senesce or die and are eliminated. Cell proliferation is necessary for growth of the organism and ensures repletion of cells lost to terminal differentiation, cell death, or cell shedding. In the case of lymphocytes, it serves the additional function of amplifying immune responses to specific antigens. Differentiation provides the organism with a supply of cells to execute specific and specialized functions. In some cell types, such as muscle and nerve cells, differentiation and proliferation are mutually exclusive fates, and cells undergo "terminal differentiation." In other cell types, such as those of the hematopoietic lineage, proliferation may continue after cells acquire differentiated characteristics. For example, erythroblasts, myeloblasts, and megakaryoblasts are committed to particular differentiation pathways and possess lineage-specific markers yet continue to proliferate. T and B lymphocytes are fully differentiated and express antigen-specific receptors but can be induced to proliferate when appropriately stimulated. Cell death is an active process when it is initiated by the cell itself in the process known as apoptosis and can be as important as cell proliferation and differentiation for maintaining the integrity of the organism. It allows tissue renewal and changes in cellular composition without undesirable cell accumulation.

When the regulation of any of these three cellular processes—proliferation, death, and differentiation—goes awry and their balance becomes abnormal, the consequences to the organism are usually dire and result in either functional insufficiency or neoplasia. The relevance of these events to normal tissue function and neoplasia has led to investigations of their mechanisms and regulation at a molecular level. This chapter focuses on cell proliferation and its regulation. Cell death is discussed in Chapter 16, and differentiation of specific hematopoietic cell types is discussed in chapters focused on these cell types.

SIGNAL TRANSDUCTION AND CELL PROLIFERATION

Cells normally proliferate and differentiate and sometimes senesce or die in response to signals from their environment. Of these, cell proliferation or mitogenic signals and signaling mechanisms are the best studied and provide a paradigm for how cells respond to environmental signals in general. Cell proliferation normally is stimulated by extracellular growth factors interacting with specific receptors located at the cell surface providing that there are sufficient nutrients to support the proliferative cellular bioenergetic needs. Signal transduction is the process by which information about growth factors at the cell surface is transmitted to the nucleus, where ultimate control of most cellular events resides. Signal transduction pathways leading to cell differentiation operate on similar principles and use similar mechanisms but produce different outcomes. A brief overview of some of the biochemical events involved in mitogenic signal transduction is provided as introduction and context for the following discussion of cell cycle regulation. A detailed discussion of signal transduction is found in Chapter 6.

Much of what is known about signal transduction is based on studies of the cellular biochemical response to mitogens such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF).[1,2] When these ligands bind to their cognate cell-surface receptors (PDGF-R and EGF-R, respectively), the receptors dimerize, activate their intrinsic tyrosine kinase activity, and catalyze the transfer of phosphate groups from adenosine triphosphate (ATP) to tyrosine residues of specific cellular proteins, including the receptors themselves (Fig. 15-1).[3] Some other types of receptors, such as the T-cell antigen receptor and CD4 and CD8 coreceptors, are not tyrosine kinases, and the tyrosine phosphorylation that they induce on ligand binding is mediated by associated nonreceptor tyrosine kinases-ZAP-70 in the case of T-cell antigen receptors and Lck in the case of CD4 and CD8.[4]

The presence of phosphotyrosines in target proteins enables them to form noncovalent complexes with proteins containing SH2 domains (Src homology region 2; defined by homology to a region in the Src retroviral oncoprotein), which are peptide domains that bind phosphotyrosine-containing peptides.[5] Thus, phosphorylation of the EGF-R and PDGF-R enables them to interact with SH2-containing proteins near or at the plasma membrane, which initiates downstream signaling events. Certain enzymes with SH2 domains, such as the γ1 isoform of phospholipase C (PLCγ1), directly associate with phosphorylated EGF-R and PDGF-R and become tyrosine phosphorylated by them, which, in the case of PLCγ1, results in enhancement of enzymatic activity. Activation of PLCγ1 catalyzes the hydrolysis of phosphatidylinositol (PIP3) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP3), both of which act as "second messengers" that launch additional actions inside cells: DAG activates protein kinase C (PKC), a kinase that phosphorylates serine–threonine residues in substrate proteins, and IP3 induces Ca^{2+} release from intracellular stores, which in turn activates Ca^{2+}/calmodulin-dependent serine–threonine protein kinases and other Ca^{2+}-dependent events.[6]

Another signaling pathway activated when mitogen receptors bind ligand and become phosphorylated stems from activation of Ras proteins. These are low-molecular-weight guanosine triphosphate (GTP)-binding proteins that are active in their GTP-bound state but inactive in their guanosine diphosphate (GDP)-bound state. The intrinsic GTPase activity of Ras, enhanced by the presence of GTPase-activating proteins (GAPs), hydrolyzes bound GTP to GDP and maintains Ras in its inactive state.[7,8] After EGF binding by EGF-R, two cytoplasmic proteins, Grb2 and SOS, that exist as heterodimers in unstimulated cells physically link EGF-R with Ras in a quaternary complex through binding of phosphorylated EGF-R with the SH2 domain of Grb2 and the binding of SOS to Ras. Formation of this complex activates the function of SOS as a guanine nucleotide exchange factor (GEF), resulting in the conversion of Ras-GDP to Ras-GTP and Ras activation. Activation of Ras initiates a cascade of serine–threonine kinase activation involving a trio of kinases.[9] Beginning with the association of GTP-Ras with Raf-1 (a mitogen-activated protein kinase [MAPK]), which activates the latter's serine–threonine kinase function, Raf-1 phosphorylates and activates MEK (MAPK kinase). MEK is a kinase that phosphorylates and activates MAPK, which is also known as ERK (extracellular signal-regulated kinase). Modules composed of three sequentially activated serine–threonine kinases are a recurring motif in signaling from the plasma membrane, where Ras and Ras-like molecules reside, to the nucleus, which phosphorylated MAPK or ERK can enter.

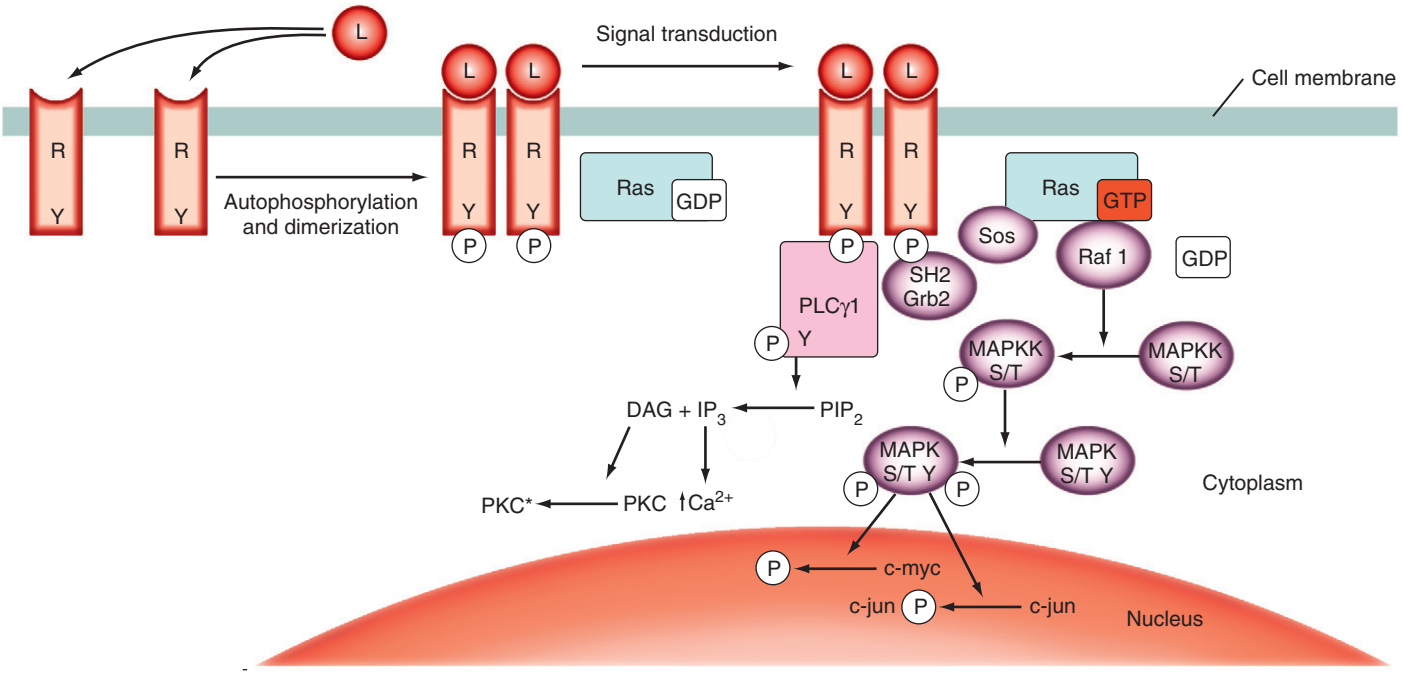

Figure 15-1 MITOGENIC SIGNAL TRANSDUCTION. Shown are signal transduction pathways activated by the binding of mitogenic ligands (L), to their cognate receptors (R) at the cell surface. Binding results in dimerization and autophosphorylation (P) of the receptors on tyrosine residues (Y). This enables them to associate with and activate specific SH2 domain-containing downstream components of the signaling pathway. In the case of phospholipase Cγ1 (PLCγ1), association leads to tyrosine phosphorylation by the receptor kinase and an enhanced ability to hydrolyze phosphoinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3); in turn, DAG activates protein kinase C (PKC) and IP_3 mobilizes Ca^{2+} from intracellular stores. In the case of Grb2-SOS, association with phosphorylated receptors stimulates its ability to facilitate Ras GTP-GDP exchange; GTP-Ras activates the MAP kinase (MAPK) cascade, which eventually induces serine (S)–threonine (T) phosphorylation of nuclear proteins that modulate gene transcription. Note that MAPK is activated by serine–threonine and tyrosine phosphorylation and that both result from the activity of a single dual-function kinase, MAPK kinase. *EGF,* Epidermal growth factor; *MAP,* mitogen-activated protein; *PDGF,* platelet-derived growth factor.

Serine–threonine kinases activated after mitogen exposure phosphorylate diverse cellular proteins and modulate their activities.[10] Prominent among these targets are transcription factors.[11] Phosphorylation may directly alter the ability of these factors to bind DNA or activate transcription. Alternatively, phosphorylation may indirectly activate transcription factors by inactivating an antagonist of these factors. Mitogen stimulation may result in activation of protein phosphatases that dephosphorylate specific phosphorylated residues in certain transcription factors to alter function.[12] The end result of these rapid posttranslational protein modifications is the first wave of change in cell transcription, which can occur independent of new protein synthesis. "Immediate early" is the description collectively applied to genes whose messenger RNA (mRNA) is rapidly induced by growth factor stimulation in the absence of de novo protein synthesis. Included in their number are genes encoding transcription factors. These initial changes lead to changes in expression of other transcription factor genes (which do require de novo protein synthesis) and culminate in the transcriptional reprogramming of the cell that eventually enables them to undergo DNA synthesis and cell cycling. It should not be surprising that many of the components of the mitogenic signaling pathway are oncogenic when they are inappropriately activated.[1]

Ligands other than EGF and PDGF may use different schemes for signal transduction. Neuroactive and vasoactive peptides (e.g., epinephrine and thrombin) activate responsive cells through specific receptors that have seven membrane-spanning domains. These receptors are typically coupled to heterotrimeric G proteins that resemble Ras in being regulated by GTP and GDP.[7,13] These receptor-coupled G proteins are linked to effector enzymes (e.g., adenylyl cyclases) that generate molecular signaling intermediates (e.g., cyclic adenine monophosphate [cAMP]) on ligand binding. Steroid and thyroid hormones and retinoids can enter cells by virtue of their lipophilic nature. Their receptors are intracellularly located and able to bind sequence-specific DNA and directly modulate the transcription of responsive genes. Thus, the receptors are transcription factors whose activities are influenced by binding of the cognate hormone.[14]

Interferon signaling uses a different signal transduction paradigm. Tyrosine kinases of the Janus kinase (Jak) family associate with interferon receptor subunits. On ligand binding, association of the receptor subunits allows these Jaks to phosphorylate and activate each other and to phosphorylate the associated receptors. Specific members of the STAT (signal transducers and activators of transcription) family of latent cytoplasmic transcription factors, which have SH2 domains, dock to the receptor phosphotyrosines and become phosphorylated by Jak. Tyrosine phosphorylation allows STATs to dimerize and translocate to the nucleus, where they bind sequence-specific DNA and modulate transcription of interferon-responsive genes.[15] Signal transduction using Jak-STAT protein is used by many peptide ligands and cytokines of hematologic interest (e.g., erythropoietin; interleukins IL-2, IL-3, IL-4, IL-6, and IL-12).

The signal transduction schemes outlined permit a single event, ligand-receptor interaction, to have several downstream consequences. Its multiplex, frequently cascading nature allows signal amplification and diversification but also permits their modulation and fine regulation. Signaling pathways can intersect and interact at different levels, allowing one ligand to modify the signals generated by another ligand. For example, STATs can be phosphorylated by receptor tyrosine kinases, such as PDGF-R and EGF-R, as well as by Jak, and can undergo serine–threonine phosphorylation, which modulates their transcriptional activity.[15] This allows PDGF and EGF to initiate some events usually initiated by cytokines and interferons, and the phenotypic changes brought about by cytokines and interferons may be altered in the presence of PDGF and EGF.

Transcription factors are final participants in afferent signal transduction pathways and initiators of cellular responses to these signals.[11] In general, they are sequence-specific DNA-binding proteins that modulate the expression of genes to which they bind. When these factors bind their cognate DNA sequence, they interact with the basal transcription machinery either directly or via intermediary proteins ("coactivators" and "corepressors") to initiate, enhance, or inhibit transcription. Transcription factors have peptide domains with characteristic secondary structures that are responsible for their ability to bind DNA. Many bind DNA only as dimers, making the peptide domain responsible for dimerization essential for DNA binding.

Transcription factors use one of a number of peptide motifs to dimerize and bind DNA, among them the zinc finger, the basic region-leucine zipper (bZip), the basic region–helix–loop–helix (bHLH), and the helix–turn–helix motifs.[16] Factors that activate gene transcription generally do so because they have a distinct transcriptional activation domain that is frequently acidic in nature, glutamine rich or proline rich. Transcriptional gene regulation is highly complex, not only because of the multitude of transcription factors present in cells but also because of the ability of many factors to heterodimerize and form combinatorial pairs that have DNA-binding, transactivation, or regulatory properties that differ from those of the parental homodimers. A striking example is provided by heterodimers containing the Id protein, which is an HLH protein that can dimerize with selected bHLH proteins, such as the myogenic transcription factor MyoD, but that does not possess a DNA-binding basic region. Id-containing heterodimers are incapable of binding DNA, making Id a negative transcriptional regulator that inhibits the function of positive factors.

Negative gene regulation also occurs by active repression of transcription, and certain transcriptional repressors have been shown to recruit factors that bind histone deacetylases. Histones are a family of nuclear proteins that interact with DNA and organize it into higher order structures consisting of DNA wrapped around a histone core (nucleosomes). Acetylation of histones masks their basic residues, destabilizes their interaction with DNA, "loosens" nucleosome DNA, and facilitates transcription. Deacetylation of histones, in contrast, stabilizes their interaction with DNA, which "tightens" nucleosome DNA and inhibits transcription. Reversible, regional histone acetylation, through recruitment of coactivators with acetyltransferase activity or recruitment of corepressors with deacetylase activity, is a general mechanism by which transcription factors facilitate or repress expression of specific genes.[17]

THE CELL DIVISION CYCLE

A cell stimulated to divide passes through a series of states, defined by biochemical and morphologic criteria, collectively termed the *cell cycle* (Fig. 15-2). Passage through the cell cycle provides an ordered sequence to the complex series of events necessary for the production of two identical progeny cells. The normal cell cycle is divided into discrete and sequential phases: S, G_2, M, and G_1.

S Phase

S phase is the period of wholesale DNA synthesis during which the cell replicates its genetic content; a normal diploid somatic cell with a 2N complement of DNA at the beginning of S phase acquires a 4N complement of DNA at its end. (Recall that N = 1 copy of each chromosome per cell [haploid]; 2N = 2 copies [diploid].) The duration of S phase may vary from only a few minutes in rapidly dividing, early embryo cells to a few hours in most somatic cells. Early embryo cells generally "live off" the accumulated stores of maternal RNA and proteins present in the egg and are transcriptionally silent, but cells in later development and mature organisms must actively transcribe subsets of their genes to survive and maintain specialized functions. The longer time required for the latter to complete S phase probably allows these cells to coordinate DNA replication with transcription and to preserve higher order gene and chromatin structural information that influences gene expression for transmission to progeny cells.

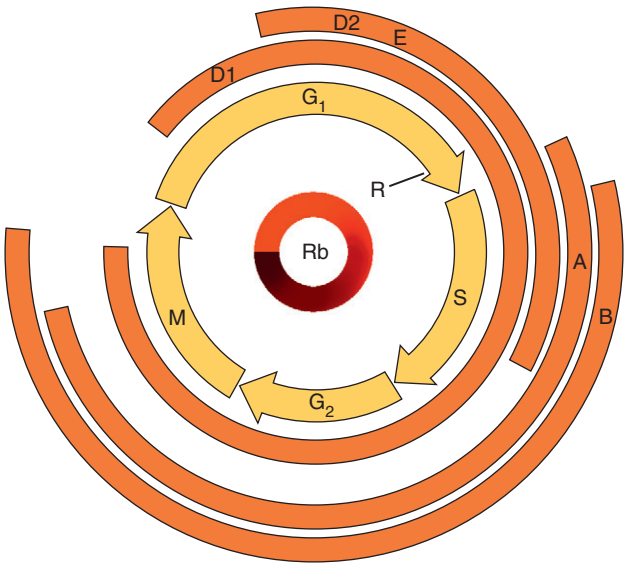

Figure 15-2 THE CELL CYCLE. The somatic cell cycle is divided into phases of DNA replication (S), mitosis (M), and the "gaps" in between (G_1 between M and S; G_2 between S and M). G_0 is not shown for the sake of simplicity but would be a side loop exiting and entering G_1. The point in late G_1 at which cells become committed to DNA replication is called the restriction point (R). The *inner circle* shows the pattern of Rb phosphorylation through the cell cycle, with the density of stippling indicating the degree of Rb phosphorylation. Places in the cell cycle where individual cyclins (A, B, D1, D2, E) appear are shown by the outer arcs.

M Phase

Mitosis, or M phase, is the period of actual nuclear and cell division during which the duplicated chromosomes are divided equally between two progeny cells. It is obvious microscopically as the period of chromosome condensation and segregation, nuclear division (karyokinesis), and physical separation of the two daughter cells (cytokinesis). A cell entering M phase has a 4N DNA content and finishes as two cells, each with an identical 2N complement of DNA. The complex sequence of changes that take place allows M to be subdivided into prophase, prometaphase, metaphase, anaphase, and telophase. Prophase is the period of chromatin and chromosome condensation, centrosome separation and migration to opposite poles, and nuclear membrane breakdown. The centrosomes are microtubule organization centers that eventually give rise to the bipole mitotic spindle apparatus that will separate the sister chromatids of each duplicated chromosome. During prometaphase, chromosomes attach to microtubules of the mitotic spindle, so that sister chromatids become attached to opposite poles. In metaphase, the condensed chromosomes align at the equatorial plate. The cohesive "bond" between sister chromatids of duplicated chromosomes is dissolved, allowing anaphase, the period of sister chromatid separation, to proceed. On reaching their poles, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense, marking telophase and karyokinesis. This is soon followed by cytokinesis and exit from M.

G_1 and G_2 Phases

G_1and G_2 phases were originally conceived of as "gaps" between the distinctive M and S phases of the cell cycle. G_1, which occupies the period or gap between M and S, is the interval between the

completion of one round of cell division and initiation of the next. Its duration is the most variable, can be prolonged depending on the cell type, and is subject to regulation by environmental factors such as the availability of growth factors and nutrients. It is the period of cell growth, and a certain increase in mass usually is required before the cell initiates the next S phase.

If cell size or mass were not regulated, S phase entry might cause cells to become progressively smaller or be at risk for DNA replication errors as a result of insufficient substrates. The mechanisms of cell size regulation are beginning to emerge from studies of yeast as well as mammalian systems.[18] Cell size regulation is intimately linked to ribosome biogenesis and nutrient-sensing systems, central to which are the phosphoinositol 3-kinase (PI3K) and target of rapamycin (TOR) pathways. Yeast mutants that generate small-size cells include mutants of the *sch9* gene, whose product is homologous to mammalian Akt–protein kinase B (PKB), and *sfp1,* which encodes a transcription factor involved in ribosome biogenesis and translation. TOR was identified as a sensor of nutrients and mediator of protein synthesis. In the setting of amino acid deprivation, for example, TOR is inactivated. Inactivation of TOR in turn decreases activated S6K1, a target of TOR and a kinase that phosphorylates ribosomal protein S6 in response to proliferative signals. A decrease in TOR function also activates 4EBP, which binds to and inhibits the translational initiator eIF4E. In an intriguing line of evidence, a class of *Drosophila* small-body-size mutants, termed *Minutes*, also has been shown to be defective in ribosomal protein genes as well as in signal transduction pathways. Specifically, whereas mutations in the *Drosophila* insulin receptor, PI3K, TOR, S6K and Akt–PKB result in the *Minute* phenotype, mutation of Pten (phosphatase and tensin homolog deleted on chromosome 10), which negatively regulates the PI3K and Akt–PKB pathways, produces large flies with large cells.

Remarkably, mutations in the *Drosophila Myc* gene also resulted in fewer, smaller cells and small body size, suggesting that proto-oncogenic *Myc* regulates size as well as cell proliferation. Because *Myc* pleiotropically affects gene expression, it has emerged as an integrator of cell size regulation and cell proliferation. In particular, mammalian c-Myc regulates both cyclins and CDK genes as well as ribosomal protein genes and genes involved in translation. Overexpression of c-Myc in lymphocytes results in both cell size increase and a detectable increase in cell proliferation. However, germline mutation of myc in the mouse results in small mice that have fewer but normal-sized cells. An interpretation of these observations is that mammalian cells may be less tolerant of cell size depletion than lower metazoans. In aggregate, studies from a variety of organisms indicate that cell size regulation is linked to cell proliferation except in specialized cells that undergo endoreplication (see Specialized Cell Cycle).

As a first approximation, the amount of time a cell spends in G_1 is inversely related to its rate of proliferation. When conditions are unsuitable for proliferation (e.g., because of insufficient nutrients or absence of mitogens), cells arrest in G_1, and those that are already in S, G_2, or M usually complete the round to which they have been committed and arrest only when they reach G_1again. On the other hand, when rapid cell proliferation is mandated, as in embryos shortly after fertilization, G_1is virtually undetectable, and there is no cell enlargement. As a result, the original mass of egg cytoplasm is partitioned among thousands of cells within a few hours without a noticeable increase in size. G_1has been subdivided into segments and regulatory points based largely on the study of the proliferative response of cells to sequential application of different growth factors, nutrients, and metabolic inhibitors. From the standpoint of cell cycle regulation, a particularly important point in G_1is the restriction point, or R, which occurs near the G_1–S boundary. This is the point at which cells become committed to entering S phase, regardless of subsequent availability of growth factors or essential nutrients, and is analogous to the commitment point in the yeast cell cycle called Start.

G_2 is the period or gap between S and M when cells have finished replicating their DNA, are preparing to divide, and have a 4N DNA content. For most cells entering S phase, passage through G_2 is "automatic," and the duration of G_2 is fixed except under unusual circumstances. For example, G_2 duration can be extremely short and is essentially undetectable in rapidly proliferating, early embryonic cells.

G_0 Phase

G_0 is a nonproliferative phase in which viable cells may remain for prolonged periods. Cells in G_0 have 2N DNA content and have exited the cell cycle. They may be difficult to distinguish morphologically from cells in a prolonged G_1 phase but in some cases can be distinguished biochemically because they differ in protein and RNA metabolism. Terminally differentiated cells, such as neutrophilic granulocytes, muscle cells, and neurons, have irreversibly exited the cell cycle during the process of differentiation and are examples of cells that have irreversibly entered G_0. Other cells reversibly enter G_0 and may be induced to return to G_1 and begin cycling with appropriate stimuli. For example, hepatocytes usually are in G_0 unless partial hepatectomy induces them to proliferate to reconstitute the functional mass of the liver. Resting, antigen-specific lymphocytes are in G_0 until antigen and cytokine stimulation induces them to proliferate.

The enforced sequence G_1–S–G_2–M during normal progression through the cell cycle means that a cell must duplicate its DNA before dividing and that it must divide before duplicating its DNA again. This sequence ensures euploidy, and its enforcement maintains genetic stability. The dependence of later events in the cell cycle on successful completion of earlier events is ensured by checkpoint control mechanisms that prevent a cell that has not successfully completed one phase of the cycle from entering the next.[19,20] Certain cell types, such as megakaryocytes, become polyploid as part of their normal development and differentiation. In these cases, the normal cell division cycle script obviously is not followed: M fails to follow S, and DNA replication is allowed to repeat despite this lack of follow-through.

RB AND TRANSCRIPTIONAL REGULATION OF THE CELL DIVISION CYCLE

Progression through the different phases of the cell cycle requires successful execution of a complex series of events. Although each of these is indispensable for a cell to give rise to two identical progeny, the pivotal event during cell proliferation is the replication of its genes. Not surprisingly, therefore, entry into S phase and initiation of DNA replication constitute a highly regulated decision. Without trivializing the other processes involved in cell cycling, those preceding DNA synthesis may be viewed as ensuring that conditions warrant genome replication and preparing for it, and those following genome replication may be viewed as making sure that the products are apportioned correctly to progeny cells. The actual process of DNA replication requires the coordinate presence and activity of substrates for DNA synthesis (deoxynucleotide triphosphates), DNA-synthetic enzymes, mechanisms for copying template DNA, mechanisms for checking the integrity of the results and correcting defects if present, and mechanisms for deconstructing and reconstructing chromatin composition and chromosome structure. The task of replicating cellular DNA is complex, as are the enzymatic and regulatory mechanisms that carry them out. Cells entering S phase must possess the proteins and substrates necessary for DNA synthesis (acquiring substrates essentially means acquiring the relevant biosynthetic enzymes), so S phase entry can happen only in cells that have activated expression of genes encoding the needed proteins.

Studies of the Rb protein have revealed fundamental principles underlying transcriptional regulation of cell entry into S phase and DNA replication.[21] Rb is the product of the Rb gene, which when defective is responsible for childhood susceptibility to retinoblastoma tumors.[22] Only one functional copy of Rb is present in the germline of patients with familial susceptibility to retinoblastomas. Retinoblasts become transformed and proliferate uncontrollably when there

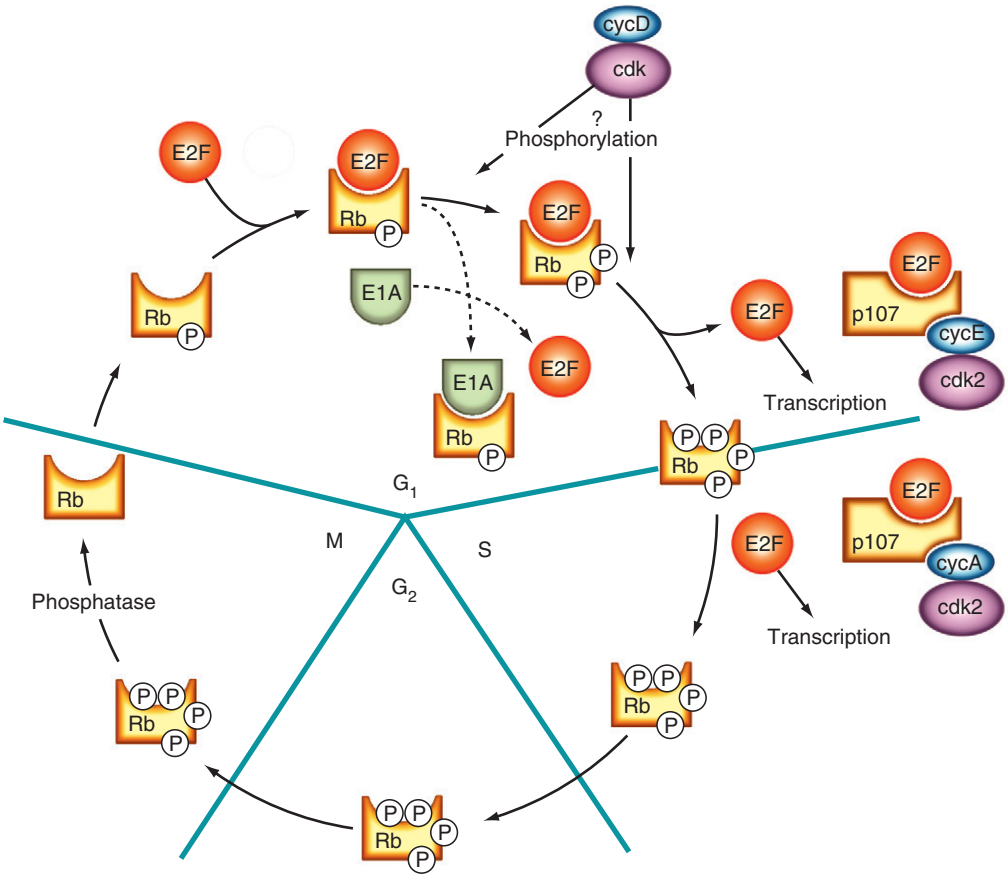

Figure 15-3 REGULATION OF THE RETINOBLASTOMA SUSCEPTIBILITY GENE PRODUCT (Rb) THROUGH THE CELL CYCLE. Rb is regulated by serine–threonine phosphorylation (P) through the cell cycle. Non- or hypophosphorylated Rb present in early and mid-G_1 can bind transcription factor E2F and thereby alter or sequester its activity. In late G_1, Rb becomes hyperphosphorylated (perhaps caused by Cdk–cyclin D kinase activity), releasing E2F for transcriptional duties or formation of other complexes. Removal of phosphate groups in M restores Rb to its hypophosphorylated form. In cells transformed by adenovirus E1A, SV40 large T, or HPV E7, these oncoproteins can bind hypophosphorylated RB and displace E2F *(dashed lines)*. The Rb-like p107 protein also binds E2F and is found in quaternary complexes with cyclin E–Cdk2 in G_1 or with cyclin A–Cdk2 in S phase.

is no functional Rb after the remaining good copy of Rb is lost or rendered nonfunctional in retinoblastoma tumor cells from these patients. This mechanism is supported by the observation that introduction of wild-type but not mutant Rb into cells without Rb causes them to arrest in G_1.[23] Thus, Rb can prevent cell entry into S phase, and retinoblastomas arise when retinoblast proliferation is no longer restrained by Rb.

Rb is widely expressed in normal cells and present at similar levels throughout the cell cycle, indicating that cell proliferation is not regulated primarily by levels of Rb protein. On the other hand, Rb phosphorylation changes markedly in different phases of the cell cycle. It is hypophosphorylated in early G_1, becomes progressively more phosphorylated on serine and threonine residues as cells progress through G_1 and approach S, and maintains this hyperphosphorylated state until M, at which time it is dephosphorylated and returned to its hypophosphorylated, early G_1 state.[24-26]

How Rb phosphorylation controls cell proliferation is understood in terms of Rb binding to transcription factors of the E2F family (Fig. 15-3).[27,28] Originally described as a cellular factor necessary for adenovirus E2 gene transcription, E2F proteins heterodimerize with members of the DP family of proteins to activate gene transcription. E2F-responsive genes include many that encode proteins necessary for DNA synthesis, such as dihydrofolate reductase, thymidine kinase, and others. Hypophosphorylated Rb binds E2F, rendering it transcriptionally inactive or an active repressor of E2F-mediated transcription.[29] Phosphorylation of serine–threonine residues in Rb near or at the site of E2F binding abrogates this interaction and Rb inhibition of E2F transcriptional activity. Thus, E2F activation of gene expression needed for S phase is inhibited by hypophosphorylated Rb in early G_1 and is reinstated as Rb becomes increasingly phosphorylated as cells progress through G_1. The importance of E2F activity for S phase transition is shown by the fact that its gratuitous expression can induce cells to enter S phase. In addition to p105 Rb (molecular mass of 105 kD), two related cellular proteins, p107 and p130, possess similar functional properties, such as the ability to bind E2F.[30] These two Rb-related proteins undoubtedly participate in cell cycle regulation, but their precise roles are still being defined.

The importance of hypophosphorylated Rb in control of cell cycling is underscored by the mechanisms tumorigenic DNA viruses use to deregulate proliferation of infected cells.[31] These viruses possess oncogenes that encode proteins responsible for transforming the infected cells. The E1A oncoprotein of adenovirus, E7 oncoprotein of human papillomavirus, and large T antigen of SV40 virus preferentially bind Rb in its hypophosphorylated state. These oncoproteins interact with Rb in the same molecular pocket as that of E2F, preventing Rb from binding E2F and permitting E2F to carry out its function unimpeded. Thus, transformation by these DNA tumor viruses is associated with cell cycle deregulation caused by viral oncoprotein inactivation of hypophosphorylated Rb function.

In the widely accepted model just described, the key to cell proliferation is release of E2F and other proteins important for S phase from Rb inhibition. This is solved in retinoblastoma and some other

tumor cell types by inactivating both copies of the Rb gene and in cells transformed by DNA tumor viruses by viral oncoproteins that inactivate hypophosphorylated Rb. Solutions that cause total, irreversible disruption of normal cell cycle regulation present no problems for tumors and help explain their growth deregulation. Normal cells needing to proliferate, however, must use a solution that can be reversed when the need has been satisfied. Their solution is use of kinases that phosphorylate Rb, which results in the progressive phosphorylation of Rb seen during passage of normal cells through G_1.

The model of Rb activity derived from study of tumors and tumor cells implies that Rb is a regulatory protein dispensable for cell cycling. The phenotype of Rb knock-out mice[32] suggests that this view also may apply in physiologic situations and during development. $Rb^{-/-}$ embryos arise in expected numbers up to day 14 of gestation but fail to develop beyond that, with evidence of abnormal central nervous system (CNS) development and defective erythropoiesis. Their development more than halfway through gestation and grossly normal appearance up to that time indicate that Rb is nonessential for cell proliferation, but the failure of CNS and erythroid development supports a role for Rb in enforcing terminal differentiation in these tissues. Neither are Rb-related p107 and p130 obligatory components of the cell cycle: Knock-out of p107 and p130 individually permits normal mouse development, and knock-out of the two in combination results in abnormal chondrocyte development and neonatal lethality.[30] Thus, Rb appears to provide a cell cycle braking mechanism that can be applied whenever circumstances dictate a stop to cell proliferation. Although the limited developmental abnormalities in $Rb^{-/-}$ embryos may be interpreted as suggesting that Rb has a rather tissue-restricted role in normal development, they more likely reflect the fact that the affected cell lineages require Rb regulatory intervention first. Rb is almost certainly part of a global regulatory mechanism for controlling mammalian cell proliferation based on the fact that the Rb pathway (involving cyclin D–Cdk4,6 and $p16^{INK4a}$ in addition to Rb, discussed next) is corrupted in many types of cancers originating in diverse tissues.

CYCLINS, CYCLIN-DEPENDENT KINASES, AND CELL CYCLE REGULATION

Discovery of the mechanisms responsible for Rb phosphorylation and mammalian cell cycle regulation had origins in studies in yeast and invertebrate and frog embryos and was aided by the phylogenetic conservation of the molecular mechanisms involved. Many of the molecules found to be important in yeast and nonmammalian cells, which can be experimentally manipulated and studied far more easily, have close counterparts and functional equivalents in mammalian cells.

Identification and subsequent functional analysis of the factors and cofactors involved in mammalian cell cycle regulation have led to the current view that progression through the cell division cycle is driven and regulated by the activity of serine–threonine kinases of the Cdk (cyclin-dependent kinase) family. As their name implies, the activity of these kinases is under the stringent control of associated regulatory proteins called *cyclins*. These were so named because levels of the first to be described, cyclins A and B, were seen to fluctuate periodically with the cell cycle. Binding to cyclins alters Cdk structure and activates their catalytic function.[33] Numerous Cdk kinases and cyclins exist in the cell, forming combinatorial pairs with distinct activities.

Control of cyclin–Cdk activity occurs at many levels. First is the appearance and disappearance of different cyclins at specific phases of the cell cycle, which dictates the cyclin–Cdk complexes that can form in each phase. Regulation at this level is a result of highly regulated synthesis and degradation of cyclin mRNA and protein at different points in the cell cycle. A second level of regulation is afforded by posttranslational modification of Cdk kinases, which is often necessary to activate their function. A third level of regulation is provided by proteins that inhibit the activity of Cdk kinases or cyclin–Cdk complexes. The importance of regulation by Cdk inhibitors is shown by the fact that cell differentiation signals often act through them to inhibit cell proliferation and by the fact that inhibitor loss allows deregulated proliferation and promotes neoplastic transformation of some cell types. When active, Cdk kinases phosphorylate other proteins involved in cell cycling, modulating their activity and behavior. Among their important functions is control of cell entry into S and M phases of the cell cycle.

ENTRY INTO S PHASE

The importance of decisions made in G_1 leading into S and their relevance to neoplastic cell behavior have made identification of regulatory factors involved in G_1 and the G_1–S transition a prime objective.[34] The molecular mechanisms regulating cell entry into S phase were first revealed by studies of a conditional cell cycle mutant of *Schizosaccharomyces pombe* (fission yeast) called *cdc2* (cell division cycle 2). Grown under nonpermissive conditions, these mutants arrest in G_1 or G_2 and cannot enter S or M. Cloning of the *cdc2* gene revealed that it encodes a 34-kD serine–threonine kinase. The structurally and functionally similar protein in mammalian cells, $p34^{cdc2}$, is the prototypical member of a family of Cdk kinases. The protein $p34^{cdc2}$ is Cdk1, and subsequently discovered members of this kinase family have been designated Cdk2, Cdk3, and so forth. Whereas $p34^{cdc2}$ is responsible for both the G_1–S and G_2–M transitions in *S. pombe,* in higher organisms, Cdk1 is involved only in G_2 and M phase events. Other Cdk kinases, such as Cdk2 and Cdk4, are the kinases important in G_1 and S in mammalian cells.

Identifying the cyclins important for G_1–S transition has been facilitated by the timing of their appearance (see Fig. 15-2). Cyclins A and B disappear during M and only reappear in S and are unlikely to have a role, but cyclins D and E are excellent candidates on the basis of timing. The candidacy of cyclins D and E is supported by their ability to functionally complement *Saccharomyces cerevisiae* (budding yeast) mutants deficient in G_1 cyclin genes *(CLN)*.[35,36] D-type cyclins were independently suspected as being important when their genes turned up during the search for an oncogene involved in parathyroid adenomas[37] and for genes induced during mitogenic stimulation of macrophages.[38] Studies indicate that D-type cyclins, of which there are three (D1, D2, and D3), associate predominantly with Cdk4 and Cdk6. Cyclin E associates with Cdk2, which also can associate with cyclin A, once it appears in S phase.

Cyclin D–Cdk4,6 and cyclin E–Cdk2 are considered the kinases primarily responsible for phosphorylating Rb and allowing cells to progress through G_1, past R in late G_1, and into S phase. Several lines of evidence support cyclin D–Cdk4,6 as regulators of G_1 progression and entry into S phase: D-type cyclins appear in early G_1 and are induced by mitogenic signals; they can phosphorylate Rb; neutralization of D-type cyclins prevents cell entry into S; and overexpression of D-type cyclins can accelerate entry into S.[39,40] D-type cyclins appear to be mitogen sensors for the cell cycle, with many steps in their accumulation being sensitive to the presence of extrinsic growth factors and mitogenic signaling. The generally accepted view is that cyclin D–Cdk4,6 complexes initiate Rb phosphorylation in mid-G_1, which leads up to the subsequent complete inactivation of Rb that is needed for the G_1–S transition. Other studies, however, have raised questions about the absolute requirement for cyclin D–Cdk4,6 in the G_1–S transition.[41,42] In mitogen-stimulated cells, cyclin E appears later in G_1, peaks near the G_1–S boundary, and declines in S (see Fig. 15-2). Cyclin E–Cdk2 associates with Rb in G_1 and can phosphorylate Rb, and inhibition of Cdk2 activity blocks cell entry into S. If all of these observations are taken into account, cyclin E–Cdk2 is probably responsible for phosphorylating Rb at additional sites in late G_1, producing a hyperphosphorylated Rb that can no longer bind E2F.

Cyclin E associates primarily with Cdk2, and the two can be found in complex with transcription factor E2F and members of the Rb family of proteins in cells in G_1. Of interest, this complex disappears as cells enter S, just as a similar complex containing cyclin A instead of E makes its appearance. Thus, cyclin A–Cdk complexes

may maintain Rb in its hyperphosphorylated state past this point in the cell cycle. Cyclin A first appears at the beginning of S and declines in G_2 and M and has an expression pattern that parallels but precedes that of cyclin B (see Fig. 15-2). These data and the results of cyclin A inhibition and addition experiments 43 have led to the view that cyclin A–Cdk2 plays a major role in driving events when cells enter S phase. Later in S and G_2, cyclin A in complex with p32cdc2 may help trigger the G_2–M transition by phosphorylating Cdc25 and initiating activation of cyclin B–p32cdc2.

ENTRY INTO M PHASE

Studies initiated in *S. pombe cdc2* mutants, which arrest in G_1 or G_2 and do not enter S or M, led to the cloning of the evolutionarily conserved $p34^{cdc2}$ (Cdk1) serine–threonine kinase.[44] An independent line of study examining the effect of cytoplasmic extracts from mature *Xenopus* frog eggs microinjected into immature frog oocytes showed that these extracts contain a material that induces oocytes to mature and undergo M phase changes such as nuclear membrane breakdown. After purification, the maturation-promoting factor (MPF) in these extracts was found to contain two proteins: One is $p34^{cdc2}$, and the other is a B-type cyclin. Cyclin B has a regulatory role in the MPF complex, shown by the fact that $p34^{cdc2}$ exhibits kinase–MPF activity only in association with cyclin B.

Cyclin B levels increase during S and G_2 (see Fig. 15-2), and levels of cyclin B–$p34^{cdc2}$ complex sufficient for the G_2-M transition are reached well before the onset of M. Mitosis is not prematurely triggered because the complex accumulates in an inactive form (Fig. 15-4). During S and G_2, the $p34^{cdc2}$ complexed with cyclin B accumulates as a multiply phosphorylated protein. In mammalian cells, phosphorylation of $p34^{cdc2}$ threonine (Thr) 161 stabilizes its association with cyclin B and is essential for activity. The kinase responsible for Thr 161 phosphorylation, CAK (Cdk-activating kinase), is itself a Cdk (designated Cdk7) that associates with a novel cyclin, cyclin H. On the other hand, phosphorylation of $p34^{cdc2}$ Thr 14 and tyrosine (Tyr) 15 suppresses its kinase activity and keeps the cyclin B–$p34^{cdc2}$ complex inactive. The kinase responsible for Tyr 15 phosphorylation is the homolog of the product of the *S. pombe wee1* gene.[45]

Activation of the cyclin B–$p34^{cdc2}$ complex is the key to cell entry into M and occurs just before M through the action of the dual-specificity phosphatase, Cdc25, causing dephosphorylation of both Thr 14 and Tyr 15. The activities of wee1 kinase and Cdc25 phosphatase are themselves regulated with phosphorylation, inhibiting

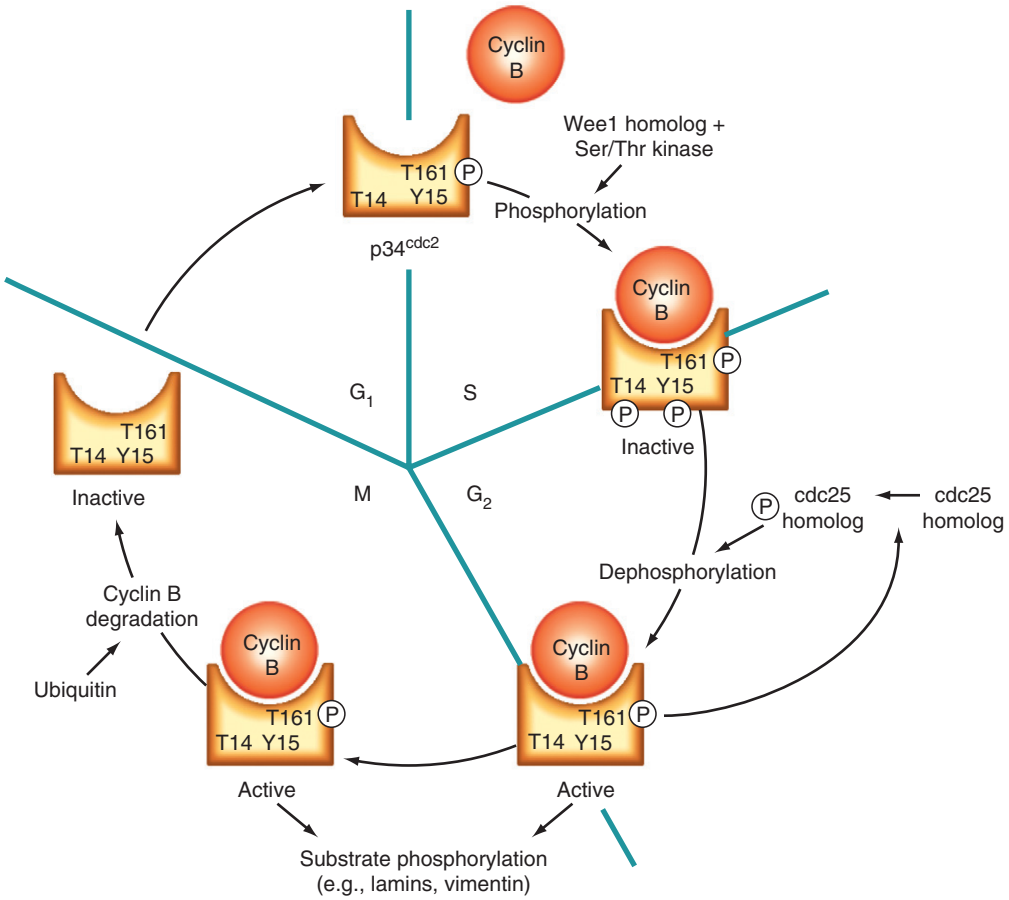

Figure 15-4 Regulation of cell entry into M by cyclin B–$p34^{cdc2}$ or Cdk1 (maturation-promoting factor [MPF]). $p34^{cdc2}$ kinase activity controls cell entry into M and is regulated during the cell cycle. Association with cyclin B, which first appears during S phase, is necessary for its kinase activity, and formation of the cyclin B–$p34^{cdc2}$ or Cdk1 complex (MPF) is stabilized by phosphorylation of Thr(T)161. Accumulating MPF is maintained in an inactive state by phosphorylation of Thr14 and Tyr(Y)15, which is catalyzed by the homolog of the *Schizosaccharomyces pombe wee1* gene product and another kinase. At the G_2–M transition, MPF is activated by dephosphorylation of Thr14 and Tyr15 by the homolog of the *S. pombe cdc25* gene product. This may be a self-amplifying reaction because activated MPF can phosphorylate and activate more Cdc25. Activated MPF phosphorylates cellular substrates and brings about the biochemical changes needed for M phase. During progression through M, degradation of cyclin B generates inactive $p34^{cdc2}$ and permits cell exit from M.

wee1 kinase function and enhancing Cdc25 phosphatase function. After a little cyclin B–p34^{cdc2} is activated, it can phosphorylate Cdc25 and create a self-amplifying feedback loop that generates more active cyclin B–p34^{cdc2} from the large preexisting stock of inactive complex.

What starts this sequence of events by initially phosphorylating and activating Cdc25 is unclear. Cyclin A–Cdk complexes have been suggested as candidates because they are active before cyclin B–p34^{cdc2} activation and have MPF activity and because inhibition of cyclin A during S prevents entry into M.[43] However, it is unclear how cyclin A–Cdk complexes, which are abundant and active throughout S, would suddenly initiate the cascade of cyclin B–p34^{cdc2} activation that marks cell entry into M phase. Polo-like kinases (PLKs), named after polo kinase, the prototypical member of this evolutionarily conserved serine–threonine kinase family,[46] are reasonable candidates because they, too, can phosphorylate and activate Cdc25 and because amplification of cyclin B–p34^{cdc2} activity does not occur until PLK becomes activated. Additionally, PLK phosphorylation of cyclin B and Cdc25 promotes nuclear localization of these proteins, enhancing nuclear accumulation of active cyclin B–p34^{cdc2} complex.[47]

Cyclin B–p34^{cdc2} can phosphorylate serine–threonine residues in many cellular proteins. Discerning its direct physiologic substrates is not simple, however, because many other kinases and cyclin–Cdk kinases are concurrently active. Candidate substrates include the lamins and vimentin, which are, respectively, nuclear and cytoplasmic proteins important for the structural organization of their compartments. These proteins undergo M phase phosphorylation and are cyclin B–p34^{cdc2} substrates in vitro. Phosphorylation of lamins is important for nuclear lamina disassembly and envelope breakdown, and phosphorylation of vimentin may cause depolymerization of vimentin intermediate filaments. If these are physiologic substrates, p34^{cdc2} –cyclin B kinase activity may initiate the structural reorganization that is essential for mitosis. PLKs, which may be phosphorylated and activated by cyclin B–p34^{cdc2}, are found at important structures and sites during M and facilitate many crucial M phase events. For example, in prophase, PLK phosphorylates cohesin and is responsible for removing most of this protein, which holds sister chromatids together after DNA replication.[48] Removal of cohesin is required for subsequent sister chromatid separation during the metaphase to anaphase transition. PLK is also needed for centrosome maturation and separation, activation of the anaphase promoting complex (APC), and regulation of cytokinesis and mitotic exit.[49]

As M phase progresses, cyclin B–p34^{cdc2} is inactivated by degradation of the cyclin B component by means of the ubiquitin pathway. A critical factor regulating its destruction is APC, the evolutionarily conserved protein complex that is responsible for ubiquitinating cyclin B and thereby targeting it for proteosome-mediated proteolysis. Low APC activity in G_2 and early M contributes to the accumulation of active cyclin B–p34^{cdc2} at those points in the cell cycle. Later in M, APC activity increases (in part owing to PLK), initiating the process of cyclin B degradation and p34^{cdc2} inactivation. Inactivation of the cyclin B–p34^{cdc2} complex is important for cell exit from M, evidenced by the fact that recombinant cyclin B that is resistant to proteolysis induces cell arrest in M. APC is important for other events during M as well. As implied by its name, APC is critical for the transition from metaphase to anaphase, when previously duplicated sister chromatids separate.[50]

INHIBITORS OF CYCLIN-DEPENDENT KINASES

Inhibitors of Cdk and cyclin–Cdk activity impose an additional layer of complexity on cell cycle regulation.[51] These inhibitors fall into two major categories. So-called "universal" inhibitors, which include p21, p27, and p57, inhibit by binding cyclin–Cdk complexes. The second group of inhibitors, which include p16, p15, p18, and p19, are more restricted in their activity and inhibit by complexing with Cdk kinases that associate with D-type cyclins (i.e., Cdk4 and Cdk6). The latter group of inhibitors are also known as INK4 because of their role as inhibitors of Cdk4.

The first inhibitor to be identified and cloned in mammalian cells was p21 (Waf1, Cip1, Sdi1), which binds several different cyclin–Cdk complexes and is the prototypical "universal" inhibitor.[52,53] The proteins p27 (Kip1) and p57 (Kip2) were subsequently identified as Cdk inhibitors with structural and functional similarities to those of p21.[54-56] The regulation of p21 expression sheds light on its function. Expression is transcriptionally induced by p53, the tumor suppressor protein activated by DNA damage (see following), and induction of p21 expression provides a mechanism for halting cell proliferation after DNA damage to allow time for damage assessment and repair.[57] The p21 protein also can be expressed in cells lacking functional p53, indicating that p53-independent pathways of expression exist. These other pathways may account for increased p21 expression in other circumstances associated with cell cycle arrest, such as senescence and terminal differentiation.

The p27 protein was originally cloned as the Cdk inhibitor associated with G_1 arrest in cells treated with transforming growth factor-β (TGFβ) or experiencing contact inhibition of growth,[54] but levels also increase in cells induced to differentiate.[58] These observations indicate that p27 often mediates the cell cycle arrest induced by extrinsic inhibitors of cell proliferation. In marked contrast with the transcriptional regulation of p21, regulation of p27 occurs posttranscriptionally, such that mRNA levels remain constant while levels of the protein change. In accordance with the ability of p21 and p27 to inhibit cyclin–Cdk activity and cell cycling, p21 and p27 are candidate tumor suppressor genes, but silencing or loss of these genes is very uncommon in cancers. However, decreased levels of p27 are seen in many carcinomas and often correlate with aggressive tumor histology and poor prognosis.[58] In some cancers, p27 levels are normal, but the protein is found in the cytoplasm rather than in the nucleus and thus unable to inhibit nuclear cyclin–Cdk complexes. Recent studies in breast cancer cells (reviewed by Blain and Massague[59]) showed that p27 is banished from the nucleus because of its phosphorylation by AKT, which is frequently constitutively active in these cells. Thus, although the *p27* gene is not genetically inactivated during oncogenesis and therefore cannot be formally counted as a tumor suppressor gene, p27 inhibition of cyclin–Cdk activity seems to be a major obstacle that cells may have to circumvent on their way to malignancy.

Cdk inhibitors p16 (INK4a, MTS1, Cdk4), p15 (INK4b, MTS2), p18 (INK4c), and p19 (INK4d) differ structurally from p21–p27 and have restricted Cdk specificity, binding only Cdk4 and Cdk6. The two founding members, p16 and p15, were cloned as tumor suppressor genes,[60] but both had previously been identified as cell cycle inhibitory proteins.[61,62] The p18 and p19 proteins were subsequently cloned based on homology to p16 and p15 and by protein interaction cloning.[63,64] Binding of these inhibitors to Cdk4 and Cdk6 prevents their association with cyclin D and their kinase activation. Because Rb family proteins are prime targets of cyclin D–Cdk4,6 kinase and phosphorylation of these proteins is crucial for G_1 progression, inhibitors of the p16 family induce cell cycle arrest in G_1. Evidence that p16 inhibits cell proliferation by preventing phosphorylation of Rb proteins is provided by the observation that p16 overexpression inhibits proliferation only of cells containing functional Rb proteins.[65] An interesting aspect of p16 expression is its upregulation in tissues of aging mice and in cultured cells approaching proliferative senescence.[66] This finding suggests a role for p16 in limiting the proliferative potential of cells in vivo and in vitro and may reflect on its activity as a tumor suppressor.

Members of the p16 family of inhibitors unquestionably have a role in preventing oncogenic transformation in vivo. This role was originally established by the cloning of the *p16* and *p15* genes from the region of chromosome 9p21 mutated in the germline of patients with familial melanoma and in the genome of many human tumor cell lines. Their importance during oncogenesis was reinforced when it was observed that *p16* knock-out mice are cancer prone[67] and by the finding that the normal *p16* and *p15* genes found in many human tumors are silenced by the epigenetic mechanism of promoter hypermethylation (reviewed by Ruas and Peters[68]). A lingering issue concerning these genes in oncogenesis stems from the fact that the 9p21 locus containing p16 also contains the *p14ARF* (in humans) or

p19ARF (in mice) genes.[69] Because these genes overlap, *p14–p19ARF* mRNA shares sequence with p16 mRNA but produces a totally different protein because of translation in an alternative reading frame (i.e., ARF). This overlap also means that many inactivating mutations of *p16* (including engineered mutations in mice) also inactivate *p14–p19ARF*. Because *p14–p19ARF* is a positive regulator of p53 expression and a tumor suppressor protein in its own right, attribution of tumor suppressor effect to each of these two genes is difficult. The more recent results of individual knock-out of each these two genes in mice indicate that loss of either *p14–p19ARF* or *p16INK4a* predisposes mice to tumors and results in abnormal regulation of cell proliferation.[70,71]

The idea that Cdk inhibitors act simply as negative regulators of kinase activity and cell cycling and that *p16–p15INK4* arrests cell cycling solely through inhibition of Cdk4,6 activity has been revised (reviewed in 1999 by Sherr and Roberts[51]). It was observed that complexes such as cyclin E–Cdk2 bound to p21–p27 were inactive but that cyclin D–Cdk4,6 complexes containing these inhibitors remained active. This suggested that the latter might sequester inhibitors while maintaining activity and prevent inactivation of Cdk2-containing complexes. Keeping cyclin E–Cdk2 active by preventing its inhibition by p21–p27 is a noncatalytic function of cyclin D–Cdk4,6 that complements and augments its catalytic function of promoting Rb hyperphosphorylation and cell cycling. In addition, p21–p27 was found to promote assembly and nuclear accumulation of active cyclin D–Cdk complexes, suggesting that the presence of these inhibitors in cyclin D–Cdk complexes may actually be facilitatory or obligatory rather than merely optional. If cyclin D–Cdk complexes are positively regulated by p21–p27 and prevent p21–p27 from inactivating cyclin E–Cdk2, the effect of p16–p15 extends beyond inhibition of Cdk4,6 complexes. In binding Cdk4,6 and preventing assembly of cyclin D–Cdk complexes, p16–p15 causes redistribution of p21–p27 onto cyclin E–Cdk2 complexes, resulting in their inactivation and an inability to hyperphosphorylate Rb. Thus, G_1 cell cycle arrest induced by p16–p15INK4 may require and be mediated by p21–p27 proteins.

CELL CYCLE CHECKPOINTS

The welfare of an organism depends on production, by its constituent cells, of normal copies of themselves during mitotic replication. If errors arise, one or both of the progeny cells develop defects in their genome that will be transmitted to successive cell generations in subsequent rounds of mitotic proliferation. Perpetuation and amplification of genetic flaws are fundamentally detrimental, and cell cycle checkpoints, which are control mechanisms that monitor and enforce proper execution of the cell division cycle, defend against development of genomic error and instability.[19]

Cell cycle checkpoints are positioned before entry into S (G_1 checkpoint), in S (S phase checkpoint), and before entry into M (G_2 checkpoint). They enforce the orderly progression of cell cycle events, such that cells must fully duplicate their DNA before they divide and divide before they duplicate their DNA again. They also check for damage sustained by genomic DNA. When problems are detected, checkpoint mechanisms interrupt cell cycling to allow correction of the problem or elimination of the defective cell. Where the mechanisms are known, cell cycling is stopped through inhibition of the cyclins and Cdk kinases that drive normal cell cycle progression. Checkpoints also exist within M, but mitotic checkpoints may exist mostly to prevent chromosome missegregation by enforcing the sequence of M phase events that distribute duplicated genetic material equally between progeny cells. The operation of checkpoints and the consequences of their failure are illustrated by yeast mutants defective in the *RAD9* gene. Although yeasts normally cannot enter M phase until their DNA is fully replicated, defects in the *RAD9* gene allow yeasts to enter M phase even if they are prevented from completing DNA replication. Affected yeasts die more rapidly because progeny inherit incomplete or damaged genetic material.

The activity of checkpoints in mammalian cells usually is observable after they have been exposed to DNA-damaging agents, such as ionizing radiation, ultraviolet (UV) light, or certain chemotherapy agents. Checkpoint activation by these genotoxic insults results in cell division cycle arrest in G_1, S, or G_2 phase, allowing cells time to repair the fault before resuming the cycle or, if the damage is irreparable, to execute a program of programmed cell death or apoptosis. Mechanisms that detect and signal the presence of damaged cellular DNA are incompletely understood, but the ATM (ataxia-telangiectasia–mutated) and ATR (AT and RAD3-related) protein kinases are clearly important components (Fig. 15-5). ATM kinase is activated by ionizing radiation and the double-strand DNA breaks it causes.[72] Defects in ATM result in cell sensitivity to ionizing radiation, defects in all DNA damage-induced cell cycle checkpoints and susceptibility of

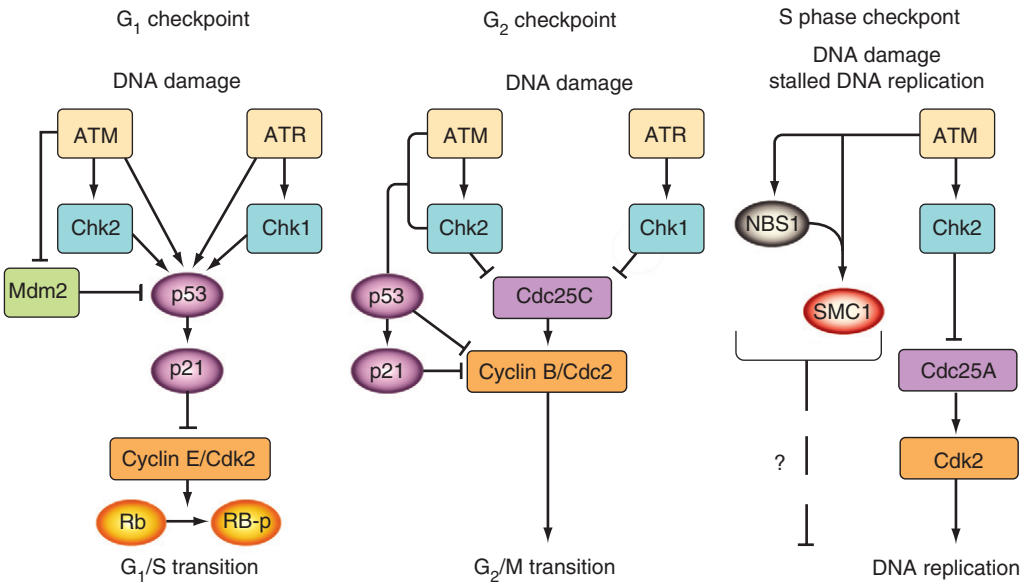

Figure 15-5 CELL CYCLE CHECKPOINTS. Pathways for activating G_1, G_2, and S phase checkpoints are shown. Arrows (Ø) designate activating interactions, and (⊣) designate inhibitory or inactivating interactions.

patients with ataxia-telangiectasia (AT) to cancer. The ATR kinase responds to UV-induced DNA damage, to stalled intermediates of DNA replication, and to damage from ionizing radiation.

ATM and ATR, both of which bind DNA, plus other proteins with homology to proteins involved in DNA replication, are responsible for sensing damaged DNA or failed DNA replication and initiating checkpoint signaling. As ATM and ATR kinase function is activated in the process, they also transduce the signals by phosphorylating downstream effectors of the checkpoint response (reviewed by Abraham[73]). Among the recipients of ATM–ATR signaling are Chk1 and Chk2. These two structurally distinct serine–threonine kinases are phosphorylated and activated by ATM–ATR. Whereas Chk1 is regulated primarily by ATR,[74] Chk 2 is regulated primarily by ATM,[75] but other factors, such as BRCA1, clearly influence their activation in response to DNA damage.[76] When active, Chk1–Chk2 join ATM–ATR to phosphorylate and activate effectors of the checkpoint response.

Prominent among the effectors activated by these kinases is p53, the tumor suppressor protein missing or inactivated in more than 50% of human cancers and an essential component of the G_1 DNA damage checkpoint. ATM–ATR directly phosphorylate p53 and indirectly promote its phosphorylation through Chk1–Chk2 phosphorylation of p53 at additional sites. The effect of this p53 phosphorylation is protein stabilization, a result that is augmented by ATM phosphorylation of the Mdm2 protein and inhibition of its ability to direct rapid p53 turnover.[77] Through this combination of mechanisms, p53 is rapidly induced following DNA damage. A transcription factor, p53 engenders cell cycle arrest by activating transcription of p21(Waf1–Cip1–Sdi1) and inhibiting cyclin–Cdk2 activity. The pathway leading from ATM–ATR to Cdk2 inhibition activates the G_1 DNA damage checkpoint by preventing Rb hyperphosphorylation.

Enforcement of the G_2 DNA-damage checkpoint involves Chk1 and Chk2 phosphorylation of Cdc25C, allowing this phosphatase to bind the 14–3-3σ protein and be sequestered in the cytoplasm. Excluded from the nucleus, Cdc25C cannot dephosphorylate Cdc2 and activate the cyclin B–Cdc2 complex needed for M phase entry.[78] Although signaling from ATM–ATR to Chk1–Chk2 to Cdc25C is one G_2 checkpoint mechanism, p53 also plays a role. The p53 protein induces p21 and represses cyclin B and Cdc2 gene expression, reducing levels and activity of cyclin B–Cdc2 complex.[79,80] These effects, plus effects on expression of other genes, result in p53-dependent G_2 arrest after DNA damage. Because p53 induction stems from ATM–ATR activation, this pathway complements Cdc25C sequestration to provide multiple ways by which ATM–ATR activation can enact G_2 arrest.

The S phase checkpoint arrests cells that experience problems after beginning DNA replication (i.e., cells that are in S phase). It does not depend on p53 and is distinct from the G_1 checkpoint, which affects cells that have not yet entered S. When ionizing radiation fails to activate this checkpoint, it results in the phenomenon of radioresistant DNA synthesis (RDS), whereby cells inappropriately continue to initiate new origins of DNA replication and replicate DNA despite DNA damage. ATM plays an important role in this pathway, evidenced by the fact that AT cells display RDS. ATM activates S phase arrest via Chk2, which phosphorylates Cdc25A and accelerates its degradation. Cdc25A normally dephosphorylates Cdk2, activating this kinase and allowing it to promote assembly of replication initiation complexes at replication origins. The inability of ATM-deficient cells to downregulate Cdc25A results in their inability to curb Cdk2 activity and DNA replication in response to ionizing radiation.[81]

More recently, Chk1 also has been shown to participate in Cdc25A regulation and prevention of RDS,[82] but the mechanism of Chk1 activation in this situation remains to be clarified. In a parallel pathway of S phase checkpoint activation, ATM phosphorylates NBS1, the product of the gene mutated in Nijmegen breakage syndrome (NBS). NBS and AT resemble each other in the predisposition of patients to cancer and of their cells to chromosome instability, radiation sensitivity, and RDS. NBS1 is part of a protein complex that binds to and helps repair double-strand DNA breaks,[83,84] and its phosphorylation by ATM is important for inducing S phase arrest after DNA damage and preventing RDS. Recently, the SMC1 (structure maintenance of chromosomes-1) protein, which has a role in chromosome structure and DNA repair, was found to be phosphorylated by ATM after ionizing radiation exposure. Phosphorylation depended on NBS1 and was important for S phase checkpoint activation.[85,86] Although many details are still unclear, ATM–NBS1–SMC1 and ATM–Chk2–Cdc25A appear to provide parallel and cooperative pathways for S phase checkpoint activation.[87]

The importance of checkpoint mechanisms is shown by the fact that mutant yeasts defective in checkpoint genes and proteins exhibit difficulties with mitotic replication, genomic instability, and death. In mammals, the consequences of failed checkpoint mechanisms can be just as devastating. *ATR* knock-out in mice is lethal at a very early stage (7.5 days) of embryonic development, with cells cultured from the embryos exhibiting loss of genomic integrity and widespread death by apoptosis.[88] Defective checkpoint mechanisms compatible with survival beyond birth, such as loss of *ATM* or *NBS1,* must have less catastrophic consequences but nevertheless produce growth retardation and developmental abnormalities.[89-91] Because organisms deficient in ATM or NBS1 survive, the impact of these proteins on neoplasia can be seen. Deficient mice and humans are predisposed to neoplasia, especially the development of thymic lymphomas. Some humans and mice heterozygous for *ATM* mutations (carriers) also are prone to developing cancers.[92,93] This occurs when the mutant *ATM* allele produces nonfunctional protein that inhibits the function of normal ATM present in the cells (i.e., exerts a dominant-negative effect).

Mutation of *p53* is the single most common genetic abnormality leading to cancer and may best illustrate the importance of checkpoint effector mechanisms as safeguards against neoplasia. p53 knock-out mice and humans heterozygous for mutated *p53* (Li-Fraumeni syndrome) have no developmental abnormalities but are predisposed to the development of a variety of malignancies. This predisposition may not be solely caused by defective p53-dependent checkpoint mechanisms, however, because p53 also has apoptosis-activating functions, and defective p53-dependent apoptotic mechanisms are known to contribute to neoplasia. The fact that p53 is important for both cell cycle arrest and apoptosis makes it almost certain that p53 plays a critical role in the cell's decision whether or not to die following genotoxic damage. In view of the fact that radiation therapy and many types of cancer chemotherapy act by damaging cellular DNA, the death or repair response of cells after genotoxic insults has impact beyond tumor development and also may influence tumor response to cancer therapy.

CELL CYCLE ALTERATIONS WITH DIFFERENTIATION

The cell cycle machinery regulates the normal proliferation of cells for both maintenance and replacement purposes. For example, blood cells, skin cells, and the gut epithelia undergo rapid turnover and require constant maintenance of the differentiated cell pools that provide specific differentiated functions. In contrast, liver, muscle, and fat cells may be replaced or expand in response to the metabolic status of the organism or to injury. Either maintenance or replacement of the differentiated cell compartment requires an orchestrated interplay between cell cycle regulation and the cell differentiation program. Although previously thought to be mutually exclusive, cell cycle progression and cell differentiation are tightly linked in the differentiation of specific cell types.

WITHDRAWAL FROM AND ENTRY INTO THE CELL CYCLE AND CELL DIFFERENTIATION

The previous paradigm for cell differentiation suggested, on the basis of studies performed with cell lines, that cell cycle progression and cell differentiation are mutually exclusive. It has become more evident, however, that cell cycle progression is inherently necessary

for the differentiation of specific cell types. For example, the hematopoietic stem cell (HSC) compartment is quiescent until these cells are called on by certain stresses to activate the hematopoietic differentiation program. The cell cycle inhibitors p21 and p27 participate in the regulation of HSC cycle. Using mice null for either p21 or p27, transplantation experiments have revealed distinct roles for these two cell cycle inhibitors. HSCs depleted of p21 proliferated, and the absolute number of stem cells doubled.[94] This unrestricted proliferation caused diminished self-renewal potential, resulting in hematopoietic failure in animals that received serially transplanted p21-null bone marrow. In contrast with the findings for p21, depletion of p27 does not affect stem cell numbers, but its absence increases progenitor cell proliferation and pool size.[95] The absence of p27, however, does not affect self-renewal potential. These findings indicate that HSCs differentiate through an orderly progression through the cell cycle for the generation of progenitor cells and the ensuing more differentiated lineage-specific cells.

COUPLING OF MANDATORY CELL CYCLE PROGRESSION AND CELL DIFFERENTIATION

Cell cycle progression required for cell differentiation is illustrated by a number of different systems, including lymphopoiesis, myeloerythropoiesis, and adipocyte and keratinocyte differentiation. In the case of lymphopoiesis, upstream regulators of the cell cycle such as the Myc–Max and Mad–Max transcriptional regulators permit cell cycle progression of pre-B lymphocytes for their sequential differentiation down the B-lymphocyte lineage. For example, overexpression of Mad, which blocks cell cycle progression, results in the paucity of mature B lymphocytes.[96] The fact that myeloid and erythroid hematopoiesis requires several generations of differentiating cells to proliferate further supports the requirement of concurrent cell expansion and differentiation.

Perhaps one of the best-studied models of cell differentiation is the adipocyte model. In this model, specific fibroblasts are triggered to initiate the adipogenesis program through a series of cell culture manipulations, including exposure of confluent fibroblasts to specific factors such as insulin, dexamethasone, and methylisobutylxanthine. An intriguing observation is that after exposure to these differentiation-inducing agents, there is a "mitotic clonal expansion" phase that is mandatory for adipogenesis of 3T3L1 fibroblasts.[97] During this phase, preadipocytes traverse through the G_1–S checkpoint with the concurrent activation of Cdk2 activity and turnover of p27. After several rounds of synchronous cell divisions, these cells cease to proliferate and start to express markers of adipocytes.

SPECIALIZED CELL CYCLE: ENDOREPLICATION AND DIFFERENTIATION

A special type of cell cycle progression is featured in the differentiation of cells that have high metabolic profiles required for synthesis of specific proteins, such as plasma proteins produced by hepatocytes, or for the production of platelets by megakaryocytes. Both cell types display endoreplication, or the repeated phases of DNA replication without cell division, resulting in cells that are gigantic and could have large nuclei with DNA content well over 128N.[98] Endoreplication also features prominently in specific plant and insect tissues, indicating that this mechanism is well used through evolution.

It stands to reason that endoreplicating cells permit G_1–S transition but have mechanisms to prevent entry into or completion of mitosis. Studies of many types of endoreplicating cells in fact support this notion. In particular, megakaryocytes endoreplicate in response to thrombopoietin with upregulation of cyclin D3. Overexpression of cyclin D3 results in increased megakaryocyte ploidy.[99] As suspected, megakaryocyte endoreplication occurs at levels of the mitotic cyclin B–Cdk1 significantly below levels in cells that undergo cytokinesis. Similarly, mammalian trophoblasts, which also undergo endoreplication, display increased cyclins D1, E, and A, but the levels of cyclin B are diminished. These observations indicate that depending on the specific cell types, cell cycle progression may be critically required for differentiation of specialized cells.

CHAPTER 16

CELL DEATH

Nika N. Danial and David M. Hockenbery

Cell death is a highly organized fundamental activity that is equally complex in regulation as cell division and differentiation. In the physiologic contexts of embryonic development and tissue renewal, or as a pathologic response to cell injury and infectious pathogens, cell deaths are orchestrated for multiple purposes that benefit the organism. These include maintenance of epithelial barrier function, destruction of microbes, adaptive immune responses, recycling of biologic macromolecules, intracellular signaling, and preservation of genomic integrity. The majority of mammalian cell deaths have morphologic and biochemical features of apoptosis (Fig. 16-1), a self-inflicted death program encoded in the genetic material of all cells (Fig. 16-2). Necrosis, an alternative mechanism of cell death, occurs in the aftermath of extreme cellular insults and could be viewed as a failure of cellular homeostasis. Recently, a programmed pathway of necrosis, referred to as *necroptosis,* has been identified. Although cells contain their own death apparatus, cell death in multicellular organisms is exquisitely sensitive to the advice and consent of neighboring cells. As might be expected, the internal cell death machinery is tightly interwoven with other essential cell pathways. Investigations of cell death have also informed our understanding of living cells (e.g., the recognition that cellular remodeling shares some pathways with apoptotic cell death).

PHYSIOLOGIC CELL TURNOVER

An adult human loses approximately 10^{11} cells/day, with skin, intestine, and hematopoietic tissues accounting for the majority. Physiologic cell death in adults occurs in the context of continuously (skin, intestine) or cyclically renewing (endometrium, breast) tissues. In most instances, homeostatic mechanisms balance generation of new cells with loss of terminally differentiated cells. In the intestinal epithelium, as an example, one stem cell per epithelial crypt asymmetrically divides to produce a daughter cell that rapidly divides, terminally differentiates (and exits from cell cycle), migrates onto the epithelium surface, and undergoes a specialized form of apoptosis that leaves behind cytoplasmic bridges that preserve epithelial barrier function, all within 2 to 3 days.

Neutrophils recruited to sites of inflammation undergo apoptosis upon removal of the inflammatory stimulus. Apoptotic neutrophils are unable to degranulate and reprogram macrophages to an antiinflammatory phenotype when phagocytosed. This clearance mechanism is specialized to apoptotic neutrophils, as necrotic neutrophils and opsonized cells trigger macrophages to secrete inflammatory cytokines.

Reversible physiologic cell deaths also provide a reserve production capacity for functionally mature cells. The glycoprotein hormone erythropoietin (EPO) is produced by kidney mesangial cells and stimulates excess red blood cell (RBC) production in proportion to the demand for blood oxygen-carrying capacity. The EPO receptor is expressed on committed erythrocyte precursors (erythroid colony-forming unit [CFU-E] and proerythroblasts). Growth factors, in general, also generate survival signals. The primary in vivo effect of EPO is to rescue erythroid precursors from physiologic death. The EPO-responsive erythroid compartment in the bone marrow is maintained at a constant size and rate of cell proliferation under various demands (hypoxia, hypertransfusion) despite widely differing production rates of mature erythroid cells. The raison d'être appears to be to overproduce CFU-Es and proerythroblasts at low altitudes with excess cells removed before the erythroblast stage; this scheme provides a rapidly accessible reserve under conditions of higher demand. Similar arrangements of excessive production with apoptosis of maturing cells are found in small intestinal crypts and spermatogenesis.

A final physiologic application for apoptosis is as a mechanism for selection of specific cell phenotypes. A well-known example occurs in the immune system after clonal diversification of T- and B-lymphocyte antigen receptors by gene recombination and error-prone DNA replication. Positive and negative clonal selection to match T-cell receptors to cognate class I and class II histocompatibility antigens on accessory cells and eliminate receptors reacting with self-antigens takes place in the thymus. Affinity maturation of immunoglobulin-bearing B cells takes place in germinal centers of lymphoid organs. In each case, cells run through a gauntlet of near-death experiences, with death and survival signals directly linked to the binding properties of the antigen receptor on individual cells.

EMBRYOGENESIS AND SCULPTING

During development, apoptosis is extensively used to sculpt the final shape of the embryo. Regression of vestigial tails, interdigital webs, and the pro- and mesonephros are all accomplished by an autophagic type of cell death with biochemical hallmarks of classical apoptosis. Certain anatomic structures, such as hollow viscus organs, are formed by apoptotic excavation of interior cell masses; the final forms of other structures, such as the forebrain, are shaped by patterns of apoptotic death within neural precursor cells. A more refined example is the matching of numbers of projecting neurons to the size of a target field, which is accomplished by apoptosis of surplus neurons. Excess or misdirected neurons fail to find the trophic factors produced by their designated targets. Localized activity of caspases may even selectively prune neural processes, leaving the neuron intact.

EXECUTIONERS OF APOPTOSIS

Caspases

The central effectors of apoptosis are a family of cysteine proteases known as caspases (cysteinyl aspartate-specific protease).[1] All caspases are aspartases with a four-residue recognition sequence P4-P1 (Fig. 16-3). A serine protease that also recognizes aspartic acid motifs, granzyme B, is similarly involved in cytolytic T-cell killing. Often only one or two caspase cleavage sites are found in a variety of cellular proteins, in many cases members of the same complex or biochemical pathway, leading to limited digestion of substrate proteins. Proteins truncated by caspase cleavage frequently exhibit altered functions,

demonstrating that caspases can act as signaling proteases. The number of identified caspase substrates is approaching 1000.[2] These can be grouped in several categories (Fig. 16-4).

Although no single caspase substrate has been identified that is obligate for cell death, some progress has been made in attributing biochemical and morphologic features of apoptotic death to proteolysis of specific substrates. Caspase-mediated cleavage and activation of Rho-associated kinase-1 (ROCK1) stimulates actin–myosin contractility, leading to membrane blebbing and fragmentation of the nucleus weakened by cleavage of nuclear lamins. DNA fragmentation is mediated by an endonuclease, DNA fragmentation factor 40 (DFF40) or caspase-activated DNase (CAD), that is activated after caspase-mediated degradation of an inhibitory binding partner, ICAD/DFF45.

In the intracellular battle between survival and proapoptotic factors, caspases can also swing the advantage toward death by altering the balance of forces. The mitochondrial survival proteins BCL-2 and BCL-X_L are subject to N-terminal cleavage by caspases. Not only does N-terminal truncation eliminate a survival function, but the cleaved versions also behave as proapoptotic factors. Activation of a proapoptotic BCL-2-family member, BH3 interacting domain death agonist (BID), also features caspase-mediated processing to a truncated factor, tBID, which then traffics to its mitochondrial site of action.

ACTIVATION OF PROCASPASES

Caspases are expressed in healthy cells as zymogens with low to absent protease activity, with association as homodimers and proteolytic processing into large and small subunits required for strong activation (Fig. 16-5). Downstream or executioner caspases (caspase-3, -6, and -7) exist as preformed dimmers.[1] Cleavage of a flexible interchain connector between subunits facilitates the movement of surface loops to form an open active site. Processing of procaspases occurs immediately after aspartate residues within caspase recognition motifs. Subsite specificities are distributed among caspases so that many caspase zymogens must be processed in trans by a different caspase, creating a hierarchy of proteolytic activation. Apical caspases (caspase-2, -8, -9, -10) have proteolytic (including autocatalytic) activity at

	Apoptosis	Necrosis

Figure 16-4 DIVERSITY OF CASPASE SUBSTRATES.

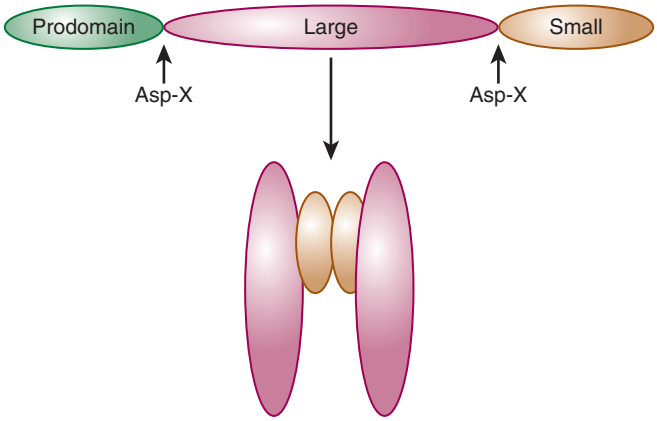

Figure 16-5 MATURE CASPASES ARE FORMED BY PROTEOLYTIC PROCESSING OF PROCASPASES TO DIVIDE LARGE AND SMALL SUBUNITS AND REMOVE N-TERMINAL PEPTIDES. Caspase substrate motifs at cleavage sites enable sequential caspase activation or, in the case of initiator caspases, autoactivation. Caspase dimers are assembled from two large and two small subunits. *Asp,* Aspartate.

high concentrations without a requirement for processing. Interactions at a dimer interface (induced proximity model) reorient and stabilize the binding pocket conformation of these caspases. Normally monomeric, these zymogens are distinguished by the presence of a long prodomain that serves as a docking site for recruitment into a self-activating complex. Protein associations within these complexes are built around homomeric interactions between three binding cassettes, the death domain (DD), death effector domain (DED), and caspase activation and recruitment domain (CARD).

DISCS, APOPTOSOMES, INFLAMMASOMES, AND PIDDOSOMES

Four distinct caspase-activating assemblies are known (Fig. 16-6). Caspase-8 and -10 are engaged by a family of cell surface receptors known as death receptors, including tumor necrosis factor receptor I (TNFR1), Fas/CD95, death receptor 4 (DR-4), and death receptor 5 (DR-5).[3,4] Ligand binding to trimerized death receptors induces conformational changes that promote binding of adaptor proteins, Fas-associated death domain protein (FADD) and TNFR1-associated death domain protein (TRADD), to the cytoplasmic tail of the death receptor by dimerization of homologous DDs from each molecule. A second interaction domain in FADD, a DED, binds to a similar DED in the prodomain of caspase-8/10, leading to caspase dimerization and localized autocatalysis. The prodomain of caspase-8/10 is severed during processing, dispersing active caspases to cellular substrates. Analysis of unprocessed caspase-8 dimers demonstrated that active sites can be formed in the absence of processing, stabilized by hydrophobic interactions at the dimer interface. The death receptor, FADD, and caspase complex is known as the death-inducing signaling complex (DISC) (see Fig. 16-6, *A*).

The second assembly, the apoptosome, is specialized for activating caspase-9, which has a CARD-type prodomain. Formation of the cytoplasmic apoptosome is initiated by release of the soluble electron carrier, cytochrome *c,* from mitochondria. Cytochrome *c* binds to an adaptor protein, apoptosis protease activating factor-1 (APAF-1), enabling adenosine triphosphate (ATP)/dATP-dependent oligomerization of APAF-1 in a heptameric wheel and exposure of its own CARD domain (see Fig. 16-6, *B*). Docking of caspase-9 to the apoptosome through CARD–CARD interactions is both necessary and sufficient for proteolytic activity. Unprocessed caspase-9 dimers contain one active site; thus, induced dimerization of caspase-9 initiates autocatalytic processing and eventual dissociation from the apoptosome with loss of proteolytic activity. Both pathways converge with proteolytic activation of caspase-3 by caspase-8, -9, or -10.

Inflammasomes are multiprotein complexes dedicated to activating caspase-1 in response to molecular cues from infectious pathogens (pathogen-associated molecular patterns [PAMPs]) or endogenous signals (danger-associated molecular patterns [DAMPs]).[5] A family of Nod (nucleotide-binding oligomerization domain)-like receptors (NLRs) detect PAMPs and DAMPs through leucine-rich repeats (LRRs), triggering oligomerization of Nod domains. A third, N-terminal region contains one of several protein interaction motifs, including CARD and pyrin domains, for direct interaction with caspase-1 or via an adaptor protein, apoptosis-associated speck-like protein containing a CARD (ASC) (see Fig. 16-6, *C*). The three inflammasomes best characterized to date are named after the NLR protein involved. Whereas NLRP1 and NLRC4 recognize bacterial muramyl dipeptide and flagellins, respectively, NLRP3 recognizes multiple stimuli, including lipopolysaccharide, bacterial RNA, and urate crystals. The inflammasome scaffold is postulated to trigger caspase-1 activity according to the induced proximity model.

Caspase-2 is activated after genotoxic damage via PIDD in a complex known as the PIDDosome. Similar to death receptors, death domains in PIDD bind to an adaptor protein, RAIDD, which in turn recruits caspase-2 through DED interactions, generating a large (>670 kD) multiprotein complex (see Fig. 16-6, *D*). PIDD also activates nuclear factor kappa-B (NF-κB) downstream of DNA damage responses through competing interactions with the receptor-interacting protein-1 (RIP1) serine/threonine kinase and I-kappa-B kinase (IKK) scaffold, NF-κB essential modulator (NEMO).

NON-APOPTOTIC ROLES FOR CASPASES

Although justifiably known for their apoptotic functions, accumulating evidence indicates that caspases also function in healthy cells.[6] Caspase-1 was originally identified as the processing enzyme for interleukin-1β (IL-1β) and recently shown to process another proinflammatory cytokine, IL-18. Caspases can also be involved in negative feedback control of erythroblast differentiation by mature erythroblasts through degradation of GATA-1. Several dramatic structural alterations associated with cell differentiation also appear to require transient caspase activation. Cleavage of a limited number of caspase substrates precede nuclear and chromatin changes during terminal erythroid differentiation, and caspase inhibitors block proplatelet formation from megakaryocytes. The more limited caspase activation in these instances may involve some degree of compartmentalization. Because the activity of unprocessed apical caspases requires persistent binding to adaptor proteins, this constraint may allow for localized, limited caspase activity under some circumstances consistent with a nonapoptotic role.

INHIBITOR OF APOPTOSIS PROTEINS

The only known endogenous caspase inhibitors are members of the inhibitor of apoptosis proteins (IAP) family. IAPs were originally described in insect viruses as viral proteins produced during cellular infection to block host cell apoptosis.[7] In mammalian cells, X-linked inhibitor of apoptosis (XIAP) is the only direct caspase inhibitor. XIAP binds to the active sites of specific caspases[3,7] to block catalytic activity or interferes with dimerization (caspase-9). IAP proteins contain one to three baculovirus IAP repeat (BIR) domains that coordinate zinc, and one or more additional protein-interaction domains. IAP-binding motifs (IBM) consist of a short peptide sequence with an amino-terminal alanine and bind to a surface groove on certain BIR domains. Initial processing of caspase-3, -7, and -9 generates an IBM at the amino-terminal end of the short subunit, providing an anchor point for additional physical interactions with IAP proteins. XIAP uses different BIR domains to bind IBMs of specific caspases.

IAPs also function as ubiquitin E3 ligases. In most cases, this function is linked to a RING domain, mediating interactions with an E2 ubiquitin conjugating enzyme. Although protein

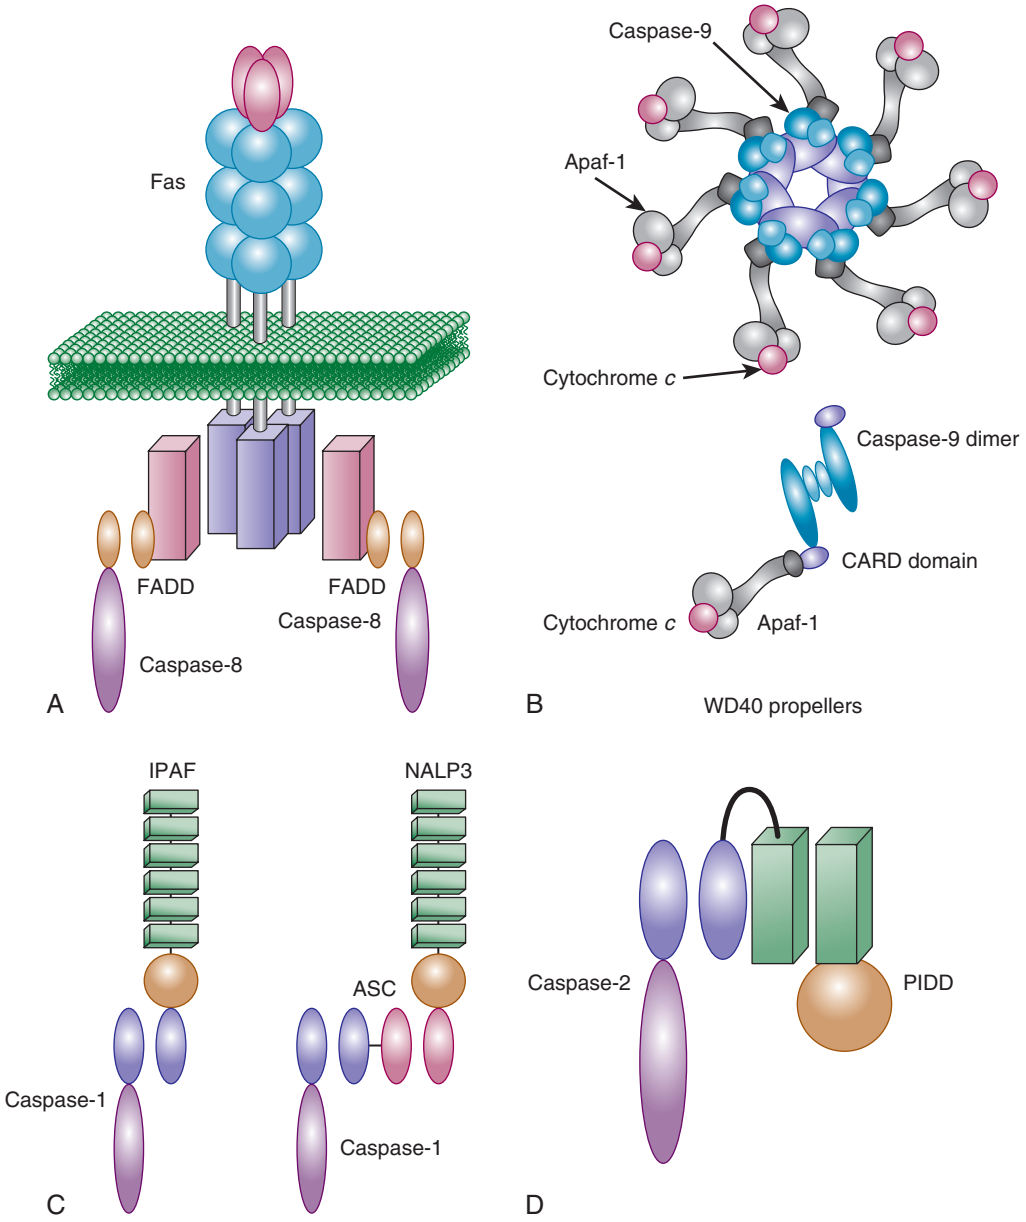

Figure 16-6 CASPASE ACTIVATION PLATFORMS. **A,** DISC (death-inducing signaling complex) is assembled after binding of ligand (Fas) to death receptor (CD95) at cell surface. Protein interaction domains (death domain [DD] and death effector domain [DED]) mediate associations between death receptor, initiator caspase (caspase-8), and adaptor protein (FADD). **B,** Apoptosome resembles a seven-spoked disc, with procaspase-9 molecules bound at the hub extending above one surface and apoptosis protease activating factor-1 (APAF-1) adaptors aligned as spokes, presenting caspase activation and recruitment domain (CARD) interaction domains at hub and WD40 propellers bound to cytochrome *c* at rim. **C,** Inflammasomes are multiprotein complexes containing either IPAF or NALPs as adaptor proteins that recruit caspase-1 and contain oligomerization domains. IPAF binds procaspase-1 through its CARD domain, and NALP-based inflammasomes recruit procaspase-1 indirectly through apoptosis-associated speck-like protein containing a CARD-1 (ASC-1), which possesses pyrin domain for NALP binding and CARD domain for caspase-1 recruitment. **D,** PIDDosome is a molecular platform consisting of the DD-containing p53-inducible protein PIDD, which binds another DD containing protein RAIDD (RIP-associated Ich-1/CED homologous protein with death domain). RAIDD recruits procaspase-2 through DD-based interactions.

degradation of polyubiquitylated caspase substrates may be involved in the apoptotic effects of XIAP, a clearer role for the ubiquitin ligase activity of IAPs has been established in NF-κB signaling.[7] TNF binding promotes assembly of a multiprotein signaling complex at the TNF-R1 receptor, including TRAF2; TRAF5; RIP1 kinase; and two IAPs, cIAP1 and cIAP2. Lysine-63 linked ubiquitylation of RIP1 by cIAP1/cIAP2 recruits two kinase complexes, IKKγ/IKKα/IKKβ and the mitogen-activated protein kinase (MAPK) TAK1/TAB2/TAB3. TAK1 phosphorylates IKKβ, which in turn phosphorylates IkB proteins, allowing NF-κB to enter the nucleus. The non-canonical pathway of NF-κB activation is also negatively regulated by cIAP1/cIAP2-mediated attachment of K48-linked polyubiquitin chains to the NF-κB–inducing kinase (NIK), leading to its degradation.

INHIBITOR OF APOPTOSIS PROTEIN ANTAGONISTS

Two proteins normally localized in the mitochondrial intermembrane space, SMAC (second mitochondria-derived activator of caspase)/Diablo and Omi/HtrA2, can bind IAPs via an NH2-terminal IBM sequence and competitively displace bound caspases. Whereas the NH2-terminus of active SMAC/Diablo is generated by removal of a presequence during mitochondrial import, Omi/HtrA2 is a stress-activated serine protease that is cleaved by autoprocessing. Cytoplasmic translocation of SMAC/Diablo and Omi/HtrA2 during apoptosis provides an additional mechanism for caspase activation. The reaper, grim, hid, and sickle proteins in *Drosophila* function similarly with fly IAPs and have NH2-terminal sequence homology to SMAC/Diablo and Omi/HtrA2.

CORE APOPTOSIS PATHWAYS

In mammals, the execution of apoptosis downstream of death signals is governed by two molecular programs that terminate in caspase activation, which may be linked in certain cell types. The extrinsic pathway operates downstream of death receptors, such as Fas and other members of the TNF receptor family, which recruit DISC upon ligand binding. This complex in turn recruits and activates caspase-8 and -10, leading to activation of other downstream caspases. The second program, also known as the *intrinsic pathway,* is marked by the involvement of mitochondria.[8-10] Besides providing most of the cellular ATP, mitochondria participate in apoptosis by releasing factors such as cytochrome *c,* a component of the mitochondrial electron transport chain. The permeabilization of the outer mitochondrial membrane (MOMP) marks the "point of no return" in the intrinsic pathway of apoptosis. After being released, cytochrome *c* is assembled with APAF-1 and caspase-9 to form the "apoptosome," which in turn triggers downstream effector caspases (see Fig. 16-6, *B*). Other apoptogenic factors released from mitochondria, including apoptosis-inducing factor (AIF), SMAC/Diablo, Omi/HtrA2, and endonuclease G, augment apoptosis.

BCL-2 FAMILY PROTEINS AND THE INTRINSIC PATHWAY OF APOPTOSIS

The BCL-2 family of proteins constitutes a critical control point in apoptosis residing immediately upstream to irreversible cellular damage, where the members control the release of apoptogenic factors from mitochondria.[8-10] Several Bcl-2 proteins reside at subcellular membranes, including the mitochondrial outer membrane, endoplasmic reticulum (ER), and nuclear membranes. The different anti- and proapoptotic members of this family form a highly selective network of functional interactions that ultimately governs the permeabilization of the mitochondrial outer membrane and subsequent release of apoptogenic factors such as cytochrome *c*. The founding member of this family, *BCL2,* was discovered as the defining oncogene in follicular lymphomas, located at one reciprocal breakpoint of the t(14;18) (q32;q21) chromosomal translocation. Cells transduced with *BCL2* remained viable for extended periods in the absence of growth factors. Transgenic mice bearing a *BCL-2-Ig* mini-gene recapitulating the t(14:18) chromosomal translocation displayed B-cell follicular hyperplasia and progressed over time to diffuse large B-cell lymphomas. BCL-2 expression specifically blocked the morphologic features of apoptosis, including the plasma membrane blebbing, nuclear condensation, and DNA cleavage. Importantly, unlike other oncogenes known at that time, BCL-2 did not promote proliferation, defining a new category of oncogenes, namely regulators of cell death. The first proapoptotic BCL2 homologous protein to be identified, BAX, co-immunoprecipitated in stoichoimetric amounts with BCL-2. *BAX*-transfected cells died rapidly in the absence of growth factor and BAX was subsequently shown to be capable of directly triggering apoptosis. Since the discovery of BCL-2 and BAX, the BCL-2 family in mammals has expanded with several acting principally as prosurvival proteins and others hastening cell death in various experimental systems (Fig. 16-7). Homologues of BCL-2 proteins exist in all metazoans studied to date as well as several animal DNA viruses.

The BCL-2 family is marked by the conserved homology domains, BH1-4 (see Fig. 16-7).[8-10] BH (BCL-2 homology) domains correspond to α-helical and connecting segments that dictate structure and function. All antiapoptotic members, such as BCL-2 and BCL-X_L, and a subset of proapoptotic family members, such as BAX and BAK, are "multidomain" proteins sharing sequence homology within 3-4 BH domains. The "BH3-only" subset of proapoptotic molecules, including BAD (BCL2 antagonist of cell death), BID, BIM (BCL2 interacting mediator of cell death), NOXA, and PUMA (p53 upregulated modulator of apoptosis), show sequence homology only within a single α-helical segment, the BH3 domain, which is also known as the critical death domain required for binding to "multidomain" BCL-2 family members. The ability of BCL-2 family proteins to selectively bind each other is integral to their function in apoptosis. The BH1, -2, and -3 domains of the antiapoptotic proteins form a hydrophobic groove that binds to the hydrophobic face of the amphipathic α-helical BH3 domain from a proapoptotic binding partner.

BAX AND BAK AND THE MITOCHONDRIAL GATEWAY TO APOPTOSIS

A combination of genetic approaches, biochemical experiments, and pharmacologic studies has begun to unravel the molecular mechanisms underlying the function of BCL-2 family proteins (Fig. 16-8). The combination of two multidomain proapoptotic members, BAX and BAK, that are absolutely required to execute death by all apoptotic signals that activate the intrinsic pathway, nominating these molecules as the requisite gateway to the mitochondrial apoptotic machinery.

Mitochondrial intramembranous homo-oligomerization of BAX and BAK is a prime candidate mechanism of MOMP that would release cytochrome *c* and involves conformational changes that result in exposure of specific epitopes. Conversely, antiapoptotic BCL-2 family members prevent the mitochondrial release of cytochrome *c*. Conformational changes during BAX and BAK activation are ultimately linked to their mitochondrial intramembranous homo-oligomerization. However, the mechanisms underlying these changes are distinct for each of these proteins. Whereas BAX is a soluble monomeric protein in the cytosol or peripherally attached to mitochondrial membrane that inserts into the mitochondrial outer membrane (MOM) upon receipt of a death stimulus, BAK is a mitochondria-resident protein (Fig. 16-9). The three-dimensional structure of inactive BAX revealed that its C-terminal tail, which is required for its insertion into the MOM, is folded back into the BAX hydrophobic cleft formed by the BH1, -2, and -3 domains. Soon after induction of apoptosis, cytosolic BAX undergoes a conformational change that releases the COOH-terminal tail, allowing BAX docking to mitochondria and exposing an NH2-terminal epitope. Membrane integrated monomers subsequently oligomerize to form pores in a manner that is dependent on the exposed NH2 terminal epitope. This is distinct from other pore-forming proteins that oligomerize before membrane insertion. Multiple conformer-specific binding partners of BAX have been identified and proposed to regulate BAX translocation, insertion, or oligomerization.[11] Among these, roles for both antiapoptotic BCL-2 proteins and BH3-only proapoptotic molecules have been proposed (see below). A growing body of evidence also shows that, in addition to protein–protein interactions, protein–lipid interactions influence BAX conformation and its ability to permeabilize the MOM.

Unlike BAX, BAK monomers are integrated into the MOM before induction of apoptosis. Select BH3-only proteins can conformational changes necessary for BAK activation. Upon activation, the

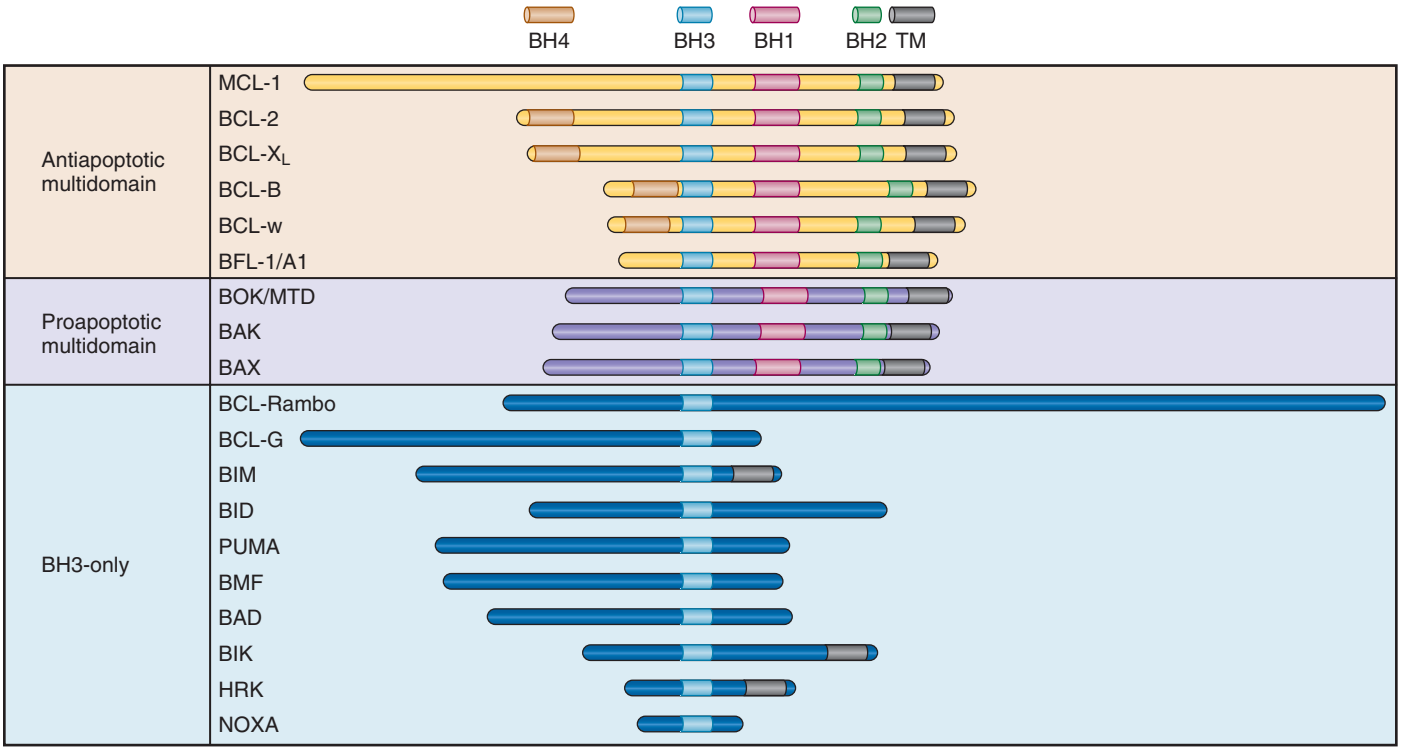

Figure 16-7 CLASSIFICATION OF BCL-2 FAMILY ACCORDING TO CONSERVED DOMAINS. BH1-3 domains form a surface hydrophobic groove capable of binding BH3 domains of other family members. BH3 domain of BAK is exposed and binds to a hydrophobic binding pocket in an adjacent BAK molecule to form a symmetric dimer. Interaction between BAK dimers may lead to higher order oligomers. Several studies suggest that membrane-activated conformers of BAX or BAK can subsequently activate other latent BAX or BAK molecules through an autoactivation mechanism, serving to amplify the signal leading to MOMP.[11]

BH3-ONLY PROTEINS

BAX and BAK oligomerization is directly or indirectly triggered by BH3-only subgroup of proapoptotic BCL-2 family members[8-10] (see Fig. 16-8). BH3-only molecules are upstream sentinels that selectively respond to proximal death and survival signals and require BAX/BAK to induce death.[12] Genetic loss of function models together with biochemical studies point to an emerging paradigm for BH3-only proteins, which consists of latent lethality requiring transcription or posttranslational modifications for activation in a tissue-restricted and signal-specific manner. Proapoptotic activity of any given BH3-only protein is associated with exposure of the hydrophobic face of its BH3 helix, enabling it to interact with the hydrophobic groove of multidomain dimerization partners. For example, cytosolic BID is activated upon cleavage by caspase-8, leading to mitochondrial translocation, BAX/BAK activation, and cytochrome *c*. On the other hand, the ability of the BH3-only molecule BAD to engage antiapoptotic BCL-2 partners is regulated though phosphorylation on three serine residues. Among the three serine sites, the phosphorylation status of serine at position 155 within the BAD BH3 domain is a critical determinant of its availability for binding to BCL-2/BCL-X_L.[13] Other BH3 proteins interact with distinct extramitochondrial targets. For example, BIM is localized to the microtubule dynein motor complex by binding to the dynein light chain, DLC1, and BMF associates with dynein light chain 2 (DLC2) in the myosin V actin motor complex. Lastly, the activation of NOXA and PUMA is under direct transcriptional regulation by p53, a finding that is consistent with their roles as specialized death sentinels during DNA damage. Thus, the large number of "BH3-only" members is indicative of specialization rather than redundancy. The unique localizations, protein associations, and mechanisms of activation for the individual proapoptotic BH3-only members BAD, BID, BIM, NOXA, and PUMA suggest that each acts as a sentinel for distinct damage signals, thereby increasing the range of inputs for endogenous death pathways.

Proapoptotic activity of BH3-only proteins is associated with exposure of the hydrophobic face of their BH3 helix, enabling it to interact with the hydrophobic groove of multidomain dimerization partners. Extensive binding studies using peptides derived from the BH3 domain of BH3-only molecules have assessed the affinities and selectivity of their interactions with multidomain BCL-2 proteins.[12] Experimental evidence based on mutational analysis, loss-of-function models and in vitro studies with isolated mitochondria has given rise to several models of how upstream BH3-only molecules directly or indirectly trigger activation of BAX and BAK to induce MOMP.[12] The complex and selective molecular interactions between the multidomain anti- and proapoptotic molecules also involve both cytosolic and membrane conformers of select family members, each of which is subjected to distinct regulatory mechanisms, including binding affinities, on/off rates, and association with membrane lipids and other binding proteins.[11]

These findings suggest that compounds capable of occupying the hydrophobic pocket of antiapoptotic BCL-2 molecules may mimic the function of sensitizer BH3-only molecules to lower the threshold for apoptosis. It has been suggested that cancer cells, which normally violate many intracellular checkpoints, already possess a significant amount of activator BH3-only molecules, "priming" these cells for death. However, antiapoptotic BCL-2 proteins are also upregulated in many cancers, sequestering the activator BH3-only molecules and

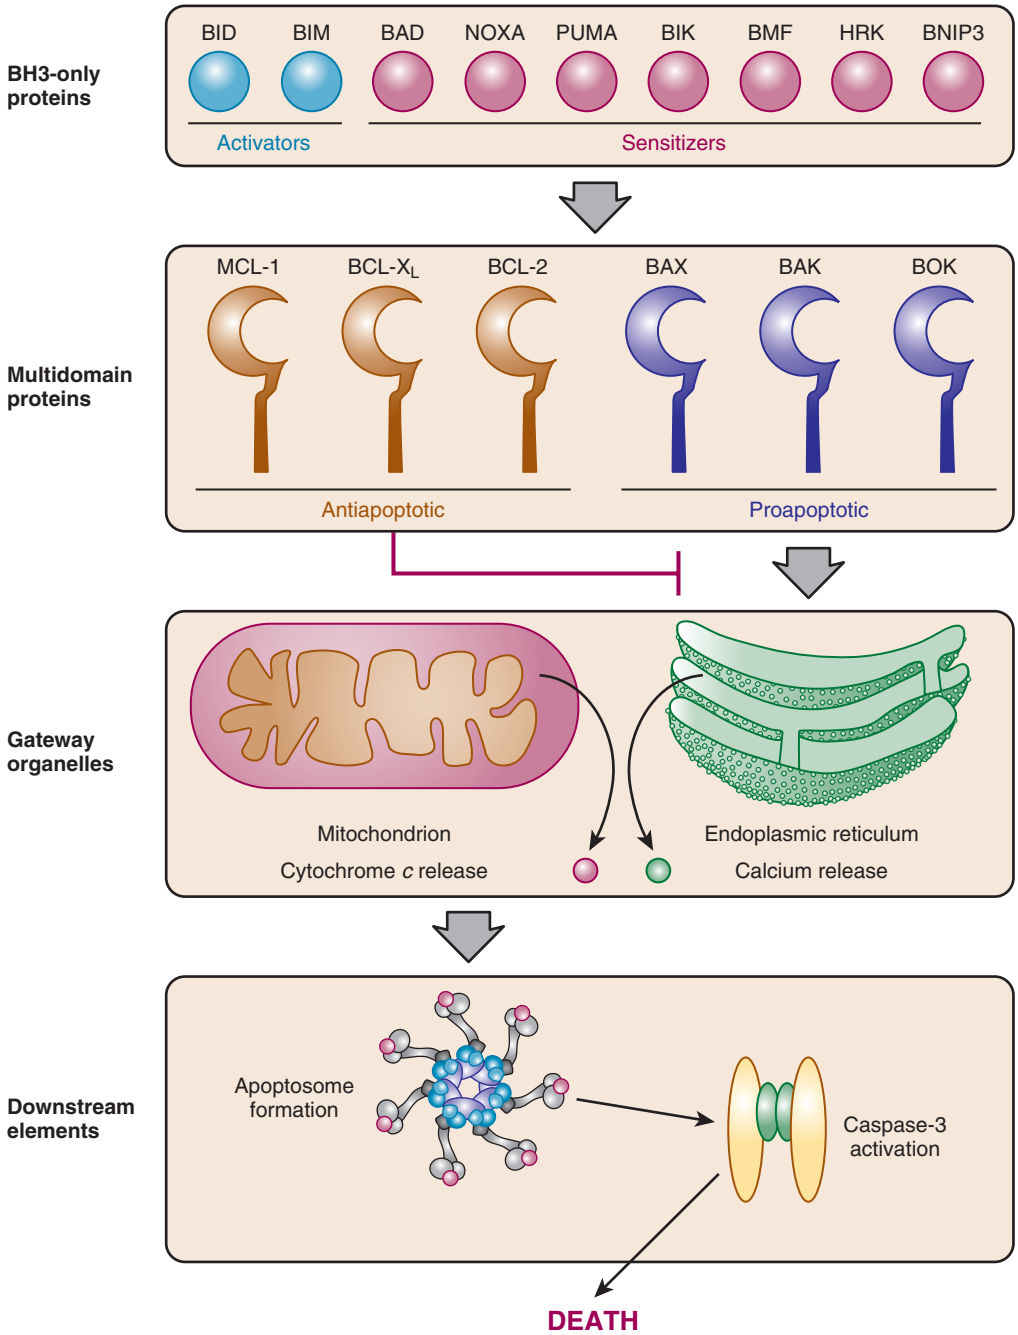

Figure 16-8 SCHEMATIC REPRESENTATION OF THE INTRINSIC APOPTOTIC PATHWAY IN WHICH A BH3-ONLY MOLECULE SERVE AS UPSTREAM SENTINELS THAT SELECTIVELY RESPOND TO SPECIFIC DEATH SIGNALS. BH3-only molecules ultimately regulate BAX and BAK (BCL2 antagonist/killer) activation directly or indirectly. This process is in turn inhibited by antiapoptotic BCL-2 family members. BAX and BAK serve as gateways to apoptosis, regulating both cytochrome *c* release from mitochondria and Ca^{2+} release from the endoplasmic reticulum (ER). See Fig. 16-7 for definitions of abbreviations.

preventing them from inducing the oligomerization of BAX/BAK. Indeed a class of small molecule inhibitors of BCL-X_L and BCL-2 mimic the sensitizer function of BAD BH3 domain and have shown efficacy in several tumor models.[14] Other approaches to manipulate the function of BCL-2 family members include peptidic compounds based on the BH3 domains of BH3-only molecules. These compounds, referred to as stabilized α-helices of BCL-2 domains (SAHBs) are generated using a synthetic strategy known as hydrocarbon stapling that allows retention of the α-helical structure and binding specificity to dimerization partners and additionally imparts membrane permeability and protease resistant properties.[15] In addition to BH3 mimetics, other approaches for manipulation of this pathway are being actively pursued.

BCL-2 FAMILY PROTEIN AND THE ENDOPLASMIC RETICULUM GATEWAY TO APOPTOSIS

Apart from cytochrome *c* release, the control of Ca^{2+} dynamics at the ER by BCL-2 family proteins has recently emerged as an important

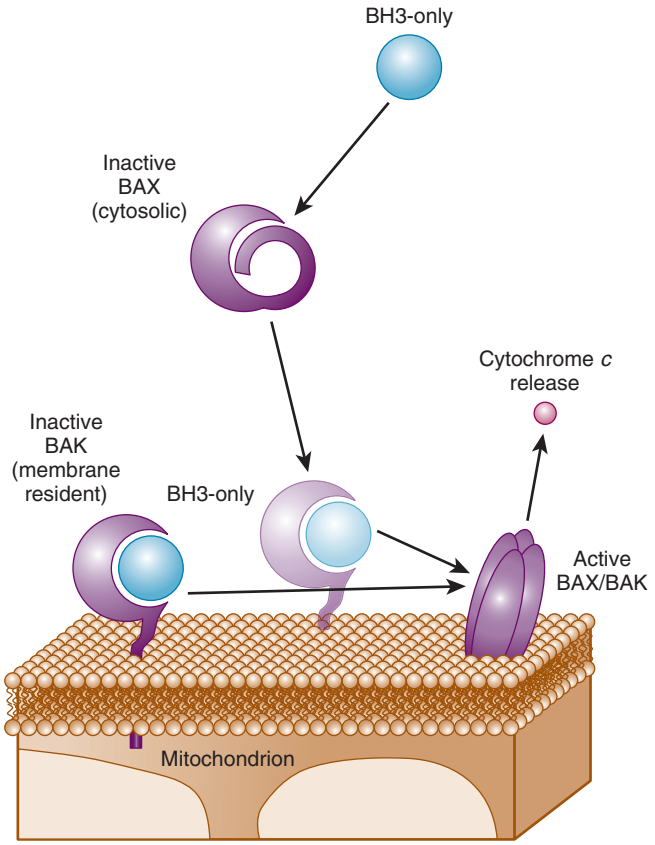

Figure 16-9 REGULATION OF BAX AND BAK (BCL2 ANTAGONIST/KILLER) OLIGOMERIZATION. BAX is a cytosolic protein that inserts into mitochondria and oligomerizes upon receipt of a death stimulus. Membrane resident BAK monomers are held in check in healthy cells and are activated to form oligomers during apoptosis.

parameter in affecting the threshold for apoptosis.[16,17] This is consistent with the ability of multiple members of this family to localize to the ER. ER Ca^{2+} content is a chief determinant of the amount of Ca^{2+} that can be released in the cytosol and thus constitutes an important regulator of Ca^{2+} signals known to control a myriad of cellular functions, including survival and death. The ER Ca^{2+} dynamics directly affect the function of mitochondria because these organelles are in close proximity, and mitochondria take up Ca^{2+} released by the ER. Ca^{2+} stimulates important enzymes in the tricarboxylic acid (TCA) cycle and influences oxidative phosphorylation and ATP synthesis by mitochondria. Supraphysiologic levels of Ca^{2+}, however, can prompt the opening of a mitochondrial innermembrane large conductance channel known as the permeability transition (PT) pore, which can eventually cause the swelling and rupture of mitochondria.

Cells overexpressing BCL-2 or deficient for both BAX and BAK show lower levels of ER Ca^{2+} and consequently lower Ca^{2+} entry into the mitochondrion. Lower ER Ca^{2+} content in these cells is associated with higher rate of ER Ca^{2+} leak. Consequently, Ca^{2+} mobilizing death stimuli specifically require the function of BAX and BAK at the ER. Genetic and pharmacologic approaches demonstrated that reduced ER Ca^{2+} content and inhibition of IP3R-mediated Ca^{2+} release is an important component of the prosurvival effect of antiapoptotic BCL-2 proteins, which is reversed by the proapoptotic members of the family. Evidence suggests that the effect of multidomain anti- and proapoptotic BCL-2 proteins on ER Ca^{2+} is likely independent of their pore-forming properties observed in synthetic membranes. Rather, modulation of ER Ca^{2+} content by BCL-2 proteins is mediated, at least in part, by their direct or indirect modulation of IP3R and SERCA.[16] The functional consequence of these interactions in regulation of ER Ca^{2+} handling and the underlying molecular mechanisms are under active investigation.

NONAPOPTOTIC ROLES FOR BCL-2 FAMILY PROTEINS

Beyond regulating apoptosis, BCL-2 family proteins may have other physiologic roles.[18] Through its association with glucokinase (hexokinase IV), the BH3-only protein BAD has been shown to regulate glycolysis, glucose-driven mitochondrial respiration, and glucose homeostasis in vivo.[13] BID, on the other hand, is a downstream substrate for DNA damage checkpoint kinases ATM/ATR and plays a role in intra-S phase checkpoint separate from its role in apoptosis. BAX and BAK influence the dynamics of mitochondrial tubules in healthy cells by controlling mitochondrial fusion and fission, processes known to dynamically control the mitochondrial network impacting the efficiency of fuel oxidation, ATP synthesis, and Ca^{2+} buffering. The above findings are but three examples of an emerging notion that BCL-2 family members are integral component of cellular homeostatic pathways and carry functions separate from their capacity to regulate apoptosis. By being embedded in these processes, they act as critical checkpoints for death when cellular homeostasis is violated.

DEATH RECEPTOR SIGNALING AND THE EXTRINSIC PATHWAY OF APOPTOSIS

Death receptors are expressed on many cell types, especially the immune system, where they have apoptotic and nonapoptotic functions, depending on cell context.[19] The cytoplasmic sequences of members of the death receptor superfamily all contain the death domain (DD 80 aa) protein-interaction motif. After being clustered by receptor–ligand interaction, the DD serves to nucleate formation of DISC for initiator caspases (caspases 8 and 10) with distinct protein interaction motifs in their long prodomains (see earlier discussion).

There are six mammalian death receptors, TNFR1, Fas, DR3, DR4 (TRAILR1), DR5 (TRAILR2), and DR6. Signaling through TNFR1 and DR3 is predominantly proinflammatory, but the remaining death receptors principally activate cell death pathways. The extracellular segments contain several cysteine-rich domains forming an extended structure stabilized by disulfide bonds. Death receptor ligands share a TNF homology domain and bind as trimers to the corresponding receptors. All known ligands are expressed as type II transmembrane proteins and are subject to limited proteolysis generating soluble forms. In most cases, soluble ligands are inferior to membrane-bound forms for receptor activation. Thus, cell–cell contacts are necessary for death-receptor signaling, justifying the characterization of subsequent apoptotic deaths as "fratricides."

In the simplest example, binding of Fas ligand to CD95/Fas receptor triggers clustering and allosteric conformational activation of an apparently trimeric receptor. An adaptor protein, FADD, binds at the Fas cytoplasmic domain using homotypic DD associations. Similarly, procaspase-8 (or procaspase-10) is bound to FADD by homotypic DED interactions. The induced proteolytic activity of procaspase-8 associated with the DISC appears to be sufficient for auto-processing in trans of neighboring procaspase molecules. A NH2-proximal cleavage separates the caspase-8 prodomain from the catalytic subunits, allowing untethering of active caspase-8 from the DISC and initiation of a cascade of effector caspase processing. Certain cells (e.g., thymocytes) can bypass Bcl-2 interdiction at the mitochondria and activate sufficient effector caspases downstream of death receptor signaling to kill cells (type I cells). Others (e.g., hepatocytes) rely on an amplification loop in which BID cleavage triggers mitochondrial apoptosis (type II cells).

Superimposed on this three-component model are additional factors that can substitute for one of the core components. FLIP (FLICE/caspase-8 inhibitory protein) is homologous to caspase-8 but devoid of protease activity (the active site cysteine is replaced). Different splice forms of FLIP retain the DED motif and compete with caspase-8 for binding to FADD. The long splice variant of FLIP, $FLIP_L$, forms heterodimers with caspase-8. Caspase-8 bound to $FLIP_L$

has catalytic activity but is processed inefficiently and remains associated with the DISC. Importantly, the caspase-8-$FLIP_L$ heterodimer is unable to cleave caspase-3 or BID. Thus, FLIP can either suppress caspase-8 activation or allow local, nonapoptotic activity. Moreover, $FLIP_L$ is also a substrate for caspase-mediated cleavage in the DISC. The cleaved product may assist with the recruitment of RIP1 kinase to the DISC, promoting activation of NF-κB and MAPKs (see above). Rapid turnover of FLIP explains the sensitization of death receptor–induced apoptosis by protein synthesis inhibition.

Recent evidence indicates that the signaling output of TNFR1 and other death receptors arises from distinct complexes.[19] The TNFR1-bound complex triggers apoptosis or NF-κB/MAPK signaling depending on the level and splice form of FLIP expressed. Notably, NF-κB upregulates expression of FLIP in a positive feedback pathway. Alternatively, a cytosolic complex lacking the TNFR1 is established after d-ubiquitination of RIP1 kinase by the CYLD deubiquitinase. This complex, designated the ripoptosome, is also capable of apoptosis signaling via caspase-8 but in the absence of caspase-8 (or presence of caspase inhibitors) triggers necroptosis, a programmed necrosis pathway characterized by cell swelling and rupture.[20] This requires association with another RIP kinase family member, RIP3. Curiously, deletion of both caspase-8 and RIP1/RIP3 is synthetically viable in mice, indicating that the embryonic lethality associated with caspase-8 is attributable to RIP1/RIP3-dependent necroptosis.[19] The downstream targets of RIP1/RIP3 in necroptosis are unknown at present. Similarly, the mechanism of caspase-8 suppression of necroptosis is unknown, although FLIP is required. Necrostatin 1, a RIP1 kinase inhibitor, is a potent inhibitor of necroptosis.[20]

Two arenas where death receptors have physiologic roles involve lymphocytes. Activation-induced cell death upon antigen restimulation involves Fas receptor signaling. Fas ligand (FasL) and Fas are induced during T-cell activation downstream of lck and NF-κB. Engagement of Fas on one cell by Fas ligand on a second cell triggers apoptosis. Autocrine suicide from FasL and Fas on the same cell has also been reported. Thus, the Fas–FasL system provides an upper limit on the density of activated T cells at sites of inflammation. Lymphocyte cell death is also directed by FasL expression on dissimilar cells. Fas expression in germinal center B lymphocytes appears to play a role in eliminating cells bearing self-reactive surface immunoglobulin because mice expressing Fas only on T lymphocytes acquire high levels of autoantibodies. In this case, FasL expression on T cells may deliver the fatal blow. T lymphocytes can also be eliminated by FasL expressed on nonlymphoid cell types.

SPECIFIC APOPTOTIC PATHWAYS

Unfolded Protein Response

Protein stress responses have been recently recognized to link into apoptotic pathways. These highly conserved mechanisms provide feedback fidelity control of protein folding, glycosylation, and secretory pathways in the ER and other subcellular compartments. Multiple inputs (amino acid deficiency, glucose deprivation, calcium dysregulation, proteasomal activity) trigger this pathway via their effects on ER protein folding. Protein stress responses are a recent addition to apoptotic pathways. These highly conserved mechanisms provide feedback fidelity control of protein folding, glycosylation, and secretory pathways in the ER.

Three protein sensors—PERK (protein kinase-like ER kinase), ATF-6 (activating transcription factor 6), and IRE1 (inositol requiring transmembrane kinase/endonuclease 1)—are triggered in response to unfolded proteins and activate a homeostatic process that reduces production of new client proteins for the ER folding machinery, helps refold misfolded proteins, and degrades protein aggregates.[21] The activity of these sensors is normally held dormant because of association with the ER chaperone BiP. During UPR, BiP is bound and sequestered by unfolded proteins, leading to derepression of each UPR sensor. PERK is activated by dimerization and autophosphorylation to subsequently phosphorylate the translation initiation factor eIF2α, leading to inhibition of general protein translation and selective increase in ATF-4 translation. The transcription factor ATF-4 in turn increases expression of select chaperones and antioxidant defense genes. ATF-6 is activated upon translocation to the Golgi and subsequent proteolytic cleavage to a fragment that translocates to the nucleus and binds the UPR response element found in the promoters of target genes. Another UPR sensor, the bifunctional protein kinase IRE1, is activated by dimerization and transphosphorylation, leading to stimulation of its inherent endoribonuclease activity and processing of mRNA encoding the basic leucine zipper transcription factor XBP-1 (X-box binding protein-1). XBP-1 together with ATF-6 regulates transcription of additional genes required for UPR, including chaperones, folding enzymes, protein disulfide isomerase (PDI), ER-associated degradation (ERAD) components, and autophagy genes. Increased ERAD components and autophagy help clear unfolded protein, protein aggregates, and damaged organelles. Remarkably, increased ER biogenesis is also part of the UPR transcriptional program to ensure sufficient ER mass matches this protein quality control response. If the integrated outcome of these signaling pathways does not salvage the ER load of unfolded and aggregated proteins, these same UPR sensors can engage the intrinsic pathway of apoptosis.[16] P53 and CHOP/GADD153, a transcription factor induced by ATF-4, initiate an ER stress-associated transcription program that is marked by changes in expression levels of several BCL-2 family members, death receptors such as FAS and DR5, and attenuation of AKT survival pathway. In addition, recruitment of the adaptor protein TRAF-2 to IRE1 may further sensitize cells to ER-stress mediated apoptosis through activation of ER-linked caspases or c-Jun-terminal kinase (JNK). JNK-1 phosphorylation of BCL-2 inhibits its survival function.

Emerging evidence from multiple experimental systems indicates that select protein modulators of UPR can be both prosurvival or prodeath depending on the extent of ER damage or the duration of UPR. The discovery of BAX and BAK association with IRE1 and modulation of its downstream effectors, such as XBP-1, suggest cross talk between BCL-2 family proteins and UPR.[22] Importantly, genetic reconstitution of DKO cells with an ER-targeted BAK restored signaling to XBP-1, suggesting that the role of BAX and BAK in UPR is distinct from their function at mitochondria. How BAX and BAK modulate IRE1 activity and signaling and whether they execute a direct role or an accessory function during each of the adaptive and protective or apoptotic phases of UPR and ER stress remain to be determined.

Oncogene-Induced Apoptosis

Hyperactivity of mitogenic oncogenes such as Myc, adenovirus E1A, and Ras triggers a common pathway of p53 accumulation via induction of the ARF tumor suppressor gene. p14ARF (or p19ARF in mice) is encoded by an alternative reading frame in the p16INK4a locus. ARF inhibits Mdm2, the p53 E3 ubiquitin ligase, and exhibits p53-independent functions, including binding to Myc and E2F transcription factors, inhibiting transactivation of target genes. The nature of the oncogenic stress leading to induction of ARF is still poorly understood but may involve DNA replication stress.

Autophagy

The main function of survival factor signaling is to support growth and proliferation through activation of metabolism, including regulation of glucose uptake, glycolysis, and mitochondrial membrane potential.[23] PI3 kinase activation downstream of growth factor receptors, including activation of the serine/threonine kinase AKT, is essential in mediating the metabolic effect of growth factors. Consequently, growth factor withdrawal is associated with a decline in metabolism, including a drop in cellular ATP levels, blunted glycolytic rates, decrease in O_2 consumption, inhibition of protein synthesis, and induction of apoptosis.

In response to such metabolic stress and nutrient starvation, the cell activates a homeostatic pathway known as autophagy (from Greek meaning to eat ["phagy"] oneself ["auto"]). Autophagy is primarily a housekeeping mechanism that normally serves to degrade long-lived proteins and damaged organelles. It involves the formation of a double membrane vesicle termed the a*utophagosome*, which engulfs cytoplasmic cargo followed by fusion with the lysosome and subsequent degradation of internal contents. Autophagy is best known as a response to starvation, in which the recycling of proteins and organelles supplies required nutrients to the cell.[24,25] This process is regulated by an evolutionarily conserved set of proteins that ultimately orchestrate the recruitment of protein and organelle cargo to vesicles that will deliver their contents to lysosomes. Autophagy serves multiple functions, including tissue remodeling during development in addition to survival in face of nutrient starvation or other environmental stress.[24,25]

The survival signaling pathway and autophagy are hardwired to preserve the cellular bioenergetic balance. Survival signaling inhibits autophagy. Downstream of AKT, the mTOR (mammalian target of rapamycin kinase) serves as a nutrient sensor that is activated by high levels of ATP, glucose, or amino acids and in turn stimulates protein synthesis and inhibits autophagy. In the presence of growth factors and extracellular nutrients, mTOR inhibits autophagy through inactivation of ATG1, an autophagy-related serine/threonine kinase that is important for autophagy induction. During nutrient starvation the activity of mTOR is inhibited by AMPK (adenosine monophosphate–activated protein kinase), another nutrient sensor kinase that is activated when the ratio of ATP to AMP decreases during metabolic stress. Through inactivation of mTOR, AMPK releases the brake on autophagy. Upon cellular metabolic decline and nutrient starvation, breakdown of organelles and proteins in autophagosomes produces amino acids and metabolites that can then feed into the mitochondrial TCA cycle, sustaining the production of $FADH_2$ and NADH, ensuring that the flow of electrons through the mitochondrial respiratory chain complexes remain uninterrupted. The bioenergetic benefits of autophagy are temporary until the metabolic stress is eliminated (e.g., growth factor or oxygen availability). Inactivation of autophagy during metabolic decline and nutrient stress leads to apoptosis unless apoptosis is inactivated (e.g., BAX/BAK deficiency), in which case cell death occurs through necrosis. Whether autophagy is primarily a form of cell death or a means of cellular survival is the subject of intense investigation. Current findings support the notion that autophagy is primarily a self-limiting survival pathway and a temporary adaptive response during metabolic stress. Current findings support the notion that autophagy is primarily a self-limiting survival pathway, which can promote cell death if not terminated.

The interrelationship between apoptosis, autophagy, and necrosis carries significant relevance in tumor settings, where defects in the apoptotic pathway (e.g., overexpression of BCL-2 or BAX/BAK deficiency) and abnormal upregulation of proliferation (e.g., constitutive activation of PI3 kinase/AKT pathway) are common.[24] Before vascularization, malignant cells in the center of tumors are exposed to hypoxia and metabolic stress, where autophagy meets the bioenergetic demands of tumor cells until vascularization supplies oxygen and nutrients. When exposed to hypoxia and nutrient limitation, such apoptosis-resistant tumor cells cannot undergo autophagy because of constitutive activation of AKT. They revert instead to necrosis, which through inflammation and stimulation of cytokine and chemokine production has been proposed to initiate a cellular repair program analogous to wound healing, further promoting proliferation and angiogenesis. Indeed, necrotic tumors are known to have a poor prognosis. These findings also explain, in part, why defects in autophagy are tumorigenic despite the notion that autophagy is primarily a survival pathway during metabolic stress.

CLINICAL APPLICATIONS

Abnormal regulation of cell death pathways is believed to contribute significantly to several diseases associated with excess cell number or function (e.g., neoplasia, autoimmune disorders) or accelerated cell loss (bone marrow failure syndromes, neurodegenerative diseases). The clearest supporting evidence is linkage to an altered gene sequence or epigenetic alteration followed by mechanism testing in cellular and animal models. As previously discussed, *Bcl-2* gene rearrangement is associated with t(14;18) in follicular B-cell lymphomas, leading to transcriptional activation and high expression levels. Mutations in the BAX coding region are found in approximately 50% of colorectal and gastric cancers associated with mismatch repair defects, representing frame-shift mutations at a poly(G)8 tract in the coding region.

One of the anticipated benefits of basic research on cell death pathways is the ability to selectively manipulate cell survival or cell death through rational drug design. Members of the Bcl-2 protein family, p53, and caspases have been targets of intensive efforts at drug discovery and design. Two small molecule inhibitors of Bcl-2 and related antiapoptotic proteins ($BCL\text{-}X_L$ and MCL-1) have advanced to phase I to II clinical trials for chronic lymphocytic leukemia, Hodgkin and non-Hodgkin lymphoma, and myelofibrosis.[26,27] These and several other inhibitors in late preclinical development bind to the hydrophobic groove in similar manner to proapoptotic BH3 peptides and are understood to act by preventing antiapoptotic proteins from sequestering proapoptotic BH3-only proteins. In addition, a broad-spectrum oxamyl dipeptide caspase inhibitor has completed phase II trials in treatment-resistant hepatitis C and orthotopic liver transplantation.[28]

FUTURE DIRECTIONS

Apoptosis is an evolutionarily conserved, highly regulated mechanism for maintaining homeostasis in multicellular organisms. Numerous signals are capable of modulating cell death. After a death stimulus, the signal is propagated and amplified through the activation of caspases, culminating in the ordered disassembly of the cell. The process may transpire through an intrinsic, mitochondria-dependent pathway, or an extrinsic pathway depending on the death signal and cell type involved. The BCL-2 family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway, providing a pivotal checkpoint in the fate of a cell after a death stimulus. The proapoptotic molecules BAX and BAK undergo an allosteric conformational activation to permeabilize mitochondria upon receipt of a death stimulus. BH3 only members connect distinct upstream signal transduction pathways with the common, core apoptotic pathway. The distribution and responsiveness of the BH3-only members suggests that they function as sentinels for recognizing cellular damage. For example, BID amplifies minimal caspase-8 activation, and BAD patrols for metabolic stress after loss of critical survival factors or glucose. This model explains how seemingly diverse cellular injuries converge on a final common pathway of cell death.

CHAPTER 17

OVERVIEW AND COMPARTMENTALIZATION OF THE IMMUNE SYSTEM

Leland D. Powell, Peter Chung, and Linda G. Baum

The human immune system is assigned the seemingly impossible role of keeping at bay the universe of pathogens seeking to invade and take advantage of the permissive conditions found in mammals for growth. It also plays a less celebrated but equally important role in the clearance of dead cells and tissues, promoting wound healing, and recognition of transformed cells. It is a complex, multilayered system that has evolved over millions of years, and early vestiges of our current immune system can be found in simple invertebrate species. The tasks assigned to it are to recognize and rapidly neutralize invading pathogens and their toxins, with minimal damage to host tissues in the process; to recognize new pathogens, including those with a high degree of likeness to the host; to discriminate between trace amounts of virulent organisms or toxins and more abundant amounts of foreign yet benign dietary or environmental structures; and to distinguish between healthy viable cells and apoptotic or necrotic cells. Disorders that are the consequence of immune under- or overreactivity are found in all medical specialties. Methods of manipulating the immune system in the areas of infectious disease, transplantation biology, autoimmunity, and tumor immunology are active frontiers of medical research and drug development.

Conceptually, the immune response may be divided into innate and adaptive systems (Table 17-1). The innate system is evolutionarily the oldest, with many components found in invertebrate species. It is a system of cells and constitutively expressed membrane-bound or soluble receptors on those cells that recognize specific pathogens without the requirement of prior exposure. Pathogen–receptor binding results in the immediate activation of specific protective humoral and cellular responses. In contrast, cells of the adaptive system do not mount an effective response on first encounter with a pathogen because of the limited numbers of antigen-specific T and B cells present in a naive host. However, recurrent infections or infections by pathogens that escape the innate immune system result in the expansion of populations of pathogen-specific lymphocytes (i.e., formation of immunologic memory). Although superficially separate, there is extensive cross-talk between the innate and humoral systems, so that pathogens that activate one lead to the recruitment and activation of the other.

The innate and adaptive immune systems have been characterized in depth at the cellular and molecular levels. The principal goal of these systems is defense against pathogens seeking entry through one of four anatomic sites: the respiratory, gastrointestinal, and genitourinary tracts and the skin. Consequently, immune function can be fully understood only by examining the anatomy of these four entry points and their relation to lymphatics, blood vessels, and lymphoid organs. This chapter provides an introduction to the molecular and cellular components of innate and adaptive immunity with an overview of their anatomic relationships.

THE INNATE IMMUNE SYSTEM

Pathogen Recognition Receptors and Pathogen-Associated Molecular Patterns

Pathogen recognition molecules or receptors (PRRs) are proteins that recognize and bind to pathogen-associated molecular patterns (PAMPs); they are the cornerstones of the innate immune response.[1,2] PAMPs are molecular motifs common to bacteria, fungi, and some viruses but not viable mammalian cells. They frequently are characterized by a repeating pattern of hydrophobic or charged molecules. Common PAMPS include lipopolysaccharide (LPS or endotoxin of gram-negative bacteria), peptidoglycans and teichoic acids (gram-positive and negative bacteria), mannans (fungi), single- or double-stranded RNA (viruses), and dsDNA (viruses or necrotic/apoptotic cells). An important feature of PAMPs is that they are derived from structures essential for the viability of the particular pathogen, properties that make them ideal targets for immune recognition by a host organism, which is accomplished by the PRRs (Table 17-2). PRRs are germ-line encoded and constitutively expressed, key features that distinguish them from the adaptive immune system. PRRs may be soluble proteins found in the serum, lymphatic fluid, or cell cytosol or as type I transmembrane proteins expressed on the surface of bone marrow (BM)–derived effector cells. They are also produced by epithelial cells in the gut,[3] bronchial airways,[4] renal tubules,[5] uterus,[6] skin,[7] and endothelial cells in the liver.[8] As such, they are poised at the four major portals of pathogen entry.

Pathogen recognition molecules or receptors encompass several different structural families (see Table 17-2). Two PRR families—peptidoglycan receptor proteins (PGRPs) and the Toll-like receptors (TLRs)—were first identified in *Drosophila* and only later demonstrated in vertebrate organisms.[9] In humans, four PGRPs have been identified and are secreted by neutrophils, hepatocytes, and epithelial cells on mucous membranes and defend against gram-positive and -negative organisms. Ten TLRs have been identified; their ligands include bacterial lipopeptides (TLR1, TLR2, TLR6), peptidoglycans (TLR2), LPS (TLR2, TLR4), fungal saccharides (TLR2, TLR6), ds- and ssRNA (TLR3, TLR7, TLR8), flagellin (TLR5), and dsDNA and CpG DNA fragments (TLR9).[10,11] Other PRR families include the C-type lectins (including the mannose-binding lectin [MBL] and pulmonary surfactant proteins),[12,13] dectin-1,[14] macrophage scavenger receptors, NOD-like receptors (NLRs),[15] and RNA helicases.[16] Many of these receptors are transmembrane proteins and function as cellular receptors and activation molecules, but others are soluble serum proteins and function by neutralizing or inducing the opsonization of pathogens. Other PRRs are found as soluble proteins within the cytoplasm of cells, where they recognize intracellular bacterial components resulting from lysosomal degradation or the products of replicating viruses (NLRs and RNA helicases).

Consequences of PRR–PAMP Ligation: Phagocytosis, the Cytokine Response, and Priming the Adaptive Immune Response

PRR–PAMP ligation triggers immune and inflammatory responses in three stages. In the first, ligation induces clearance of pathogens or foreign molecules by monocytes, macrophages, and neutrophils. This process is initiated by pathogen binding directly to PRRs on the surfaces of these cells or the opsonization of pathogens bound by a soluble PRR. Internalized pathogens are destroyed by a combination of hydrolytic and oxidation reactions within vacuoles inside the phagocytic cells. Phagocytosis also triggers degranulation and the

Table 17-1 Human Innate Versus Adaptive Immune System

Feature	Innate	Adaptive
Response time	Hours to days	>5 days
Expression	Constitutive	Induced by pathogen exposure
Shaped by pathogen exposure	No	Yes
Approximate number of gene products involved in direct pathogen recognition	10^2 to 10^3	10^{10} to 10^{14}
Clonal response	No	Yes
Found in invertebrate species	Yes	No

release into tissues of bactericidal or bacteriostatic molecules such as lysozyme, lactoferrin, myeloperoxidase, antimicrobial peptides, nitrous oxide, and superoxide radicals. These products are toxic to pathogens and induce a local inflammatory response that can lead to tissue injury. Other molecules released, including elastase and collagenase, participate in tissue injury and wound healing.[17-20]

The second stage is cytokine production. Despite the diversity of the PRRs, intracellularly they share common pathways, leading to the synthesis and secretion of proinflammatory cytokines, chemokines, and type I interferons (IFNs), molecules that are essential for the initiation, amplification, and maintenance of innate and adaptive immune responses. Many PRRs function by activating NF-κB (nuclear factor κ-light-chain-enhancer of activated B cells), but others signal through the caspases, IRF3/5/7, MyD88, and other kinase cascade pathways. Cytokines may be categorized according to similarities in cell source, receptor structure, or biologic consequences. In general, interleukins are produced by monocytes or macrophages, lymphocytes, or specialized or inflamed epithelial cells. They act on these and other cells to amplify the innate and initiate the adaptive immune responses. The INFs are produced by virtually all cells. Acting on T and natural killer (NK) cells, they propagate antiviral and antitumor responses. Chemokines are produced primarily by cells of the innate immune system and function dually as chemoattractants (i.e., recruiting cells) and cytokines (i.e., activating cells). Members of the tissue necrosis factor family mediate the sepsis response and cell death and participate in the development of lymphoid organs. A simplified organization of some of the better-characterized cytokines by biologic effects is presented in Table 17-3, and a more detailed discussion of some cytokines can be found in Chapter 14.

The final stage is activation of the adaptive immune response. Both by the production of cytokines, which activate lymphocytes, and by the processing, transport, and presentation of antigens directly to T cells (primarily done by dendritic cells [DCs]), PRRs and cells of the innate immune system are essential for the development of adaptive immune responses. The biology of T cells, B cells, and DCs is discussed in detail in Chapters 18 to 21.

IMMUNE DEFICIENCY CONDITIONS CAUSED BY MUTATIONS IN THE INNATE IMMUNE SYSTEM

Although studies in mice have been instrumental in characterizing the roles of many PRRs listed in Table 17-2, their significance to humans is established by diseases linked to naturally occurring mutations or polymorphisms in either the PRRs or their intracellular signaling molecules. For instance, 10 different MBL haplotypes have been identified with serum levels varying by up to 1000-fold. Low levels can be associated with increased severity of infections with encapsulated organisms in immunocompromised or chronically infected hosts.[21] Mutations or polymorphisms in TLRs are associated with sepsis response, asthma, and the rare immunodeficiency syndrome ectodermal dysplasia with immunodeficiency. Although the absolute absence of a molecule or a critical mutation (e.g., stop codon mutation) can certainly be viewed as a mutation, other polymorphisms are common and thus could be more accurately viewed in the continuum of phenotypic variation of the species.[22]

INNATE IMMUNITY AND TISSUE HOMEOSTASIS

Pathogen recognition molecules or receptors and cells of the innate immune system also play roles in normal tissue homeostasis. Specific PRRs are involved in the clearance of serum clotting factors, hormones, lysosomal hydrolases, senescent cells, and proteins and in wound healing.[23,24] The class A scavenger receptor on macrophages is involved in the internalization of oxidized low-density lipoprotein, the development of atherosclerosis, and the clearance of apoptotic T cells in the thymus.[12] Another aspect of tissue homeostasis is the surveillance against transformed or malignant cells, which involves IFN-γ, γδ T cells, NK cells, and cytotoxic T lymphocytes (CTLs).

ADAPTIVE IMMUNE RESPONSE

The adaptive immune response deals primarily with the generation of T-cell receptor (TCR) and B-cell receptor ([BCR] or immunoglobulin [Ig]) diversity. The adaptive system achieves two goals not met by the innate system: generation of a receptor repertoire far more diverse than that represented by PRRs and the amplification of specific populations of pathogen-specific cells as a consequence of pathogen exposure (i.e., generation of specific immunologic memory). Whereas innate immune function depends on germ line–encoded molecules, the adaptive immune response arises from somatic mutations in TCR and BCR/Ig genes that occur during T- and B-cell development. This process results in a remarkable diversification and amplification of the repertoire of pathogen-specific recognition molecules (see Table 17-1).

The complex steps involved in TCR and BCR/Ig generation require a close interplay between the innate and adaptive immune systems. A particular pathogen gaining entry through a specific anatomic site first encounters the innate defense. The initial response, which depends on PRRs, triggers the production of cytokines that activate resident DCs. DCs phagocytize and process the antigens by cleaving them into small peptides. These peptides are then presented on the DCs' surfaces bound to MHC molecules. T and B cells that recognize the processed antigens become activated and begin to divide. This antigen presentation step may occur at the site of pathogen exposure, or it may require the migration of antigen-containing DC from the point of pathogen entry through lymphatic channels to lymphoid tissues. Other consequences of the inflammatory response induced by the innate response include changes in vascular permeability, chemotaxis, and lymphocyte adhesion. These steps result in local inflammation and the recruitment of additional lymphocytes to the site of pathogen entry. DCs, B cells, and T cells are discussed in depth in Chapters 18 to 21.

CELLS OF THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

Lymphocytes

The major lymphocyte subsets are B and T cells, and NK cells are an important but less common, a specialized lymphoid population. Lymphocytes initially arise in the BM and subsequently undergo maturation in peripheral lymphoid organs (i.e., thymus for T cells and lymph nodes [LNs], spleen, or other lymphoid tissues for B cells). Subsets of T and B cells can be identified by unique surface phenotypes, a characteristic that has been useful in understanding normal biology and in the diagnosis of inflammatory or malignant conditions.

Table 17-2 Human Pathogen Recognition Receptors

Receptor	Location	Ligands or PAMPs	Features
TLRs (leucine-rich protein)	Leukocytes and some epithelial cells in bronchial airways, urogenital tract, and gut	Cell wall components of gram-positive and -negative bacteria (peptidoglycans and lipopeptides), viral dsDNAs, ds- and ssRNAs, bacterial flagellin, and other pathogen-derived molecules	A family of 10 different proteins (TLR1–TLR10) found as transmembrane proteins on the surface of cells or internal endosomes or as free cytosolic proteins; trigger cell activation and cytokine response
CD14 (leucine-rich protein)	Soluble and membrane-bound forms found on monocytes, macrophages, and endothelial cells	LPS from gram-negative bacteria	Binding of LPS on the cell surface forms a complex, including TLR4, which results in cytokine production and the sepsis response
Serum MBL (C-type lectin)	Soluble protein found in serum and lymphatic fluid	Pathogen-derived carbohydrate structures containing mannose, fucose, or *N*-acetylglucosamine	Secreted by hepatocytes; binding to pathogen triggers complement activation and assembly of the membrane attack complex
Pulmonary surfactant proteins (C-type lectin)	Soluble proteins found extracellularly on pulmonary mucosal surfaces	Carbohydrate structures or lipid motifs on viral, bacterial, or fungal pathogens and inhaled irritants, including pollens	Secreted by alveolar type II cells and nonciliated bonchiolar epithelial cells; binding to pathogen induces opsonization and leukocyte activation (including alveolar macrophages)
Macrophage mannose receptor (C-type lectin)	Surface of monocytes and macrophages	Pathogen-derived carbohydrate structures similar to MBP	Ligand binding results in phagocytosis and monocyte or macrophage activation
NKG2 (C-type lectin)	Surface of NK cells	Carbohydrates on HLA molecules or other host molecules	Involved in recognition and destruction of virally infected or transformed host cells
Dectin-1 (C-type lectin)	Surface of macrophages, neutrophils, and DCs	β-Glucan structures on fungi and plants	Binding results in cell activation, cytokine production, and internalization of pathogen
Class A scavenger receptors (SR-A I/II/III) (Scavenger receptor family)	Monocytes, macrophages, and epithelial cells	Modified, cell wall components of gram-positive and -negative organisms	Phagocytosis of nonopsinized particles and macromolecules triggers macrophage activation and cytokine release; plays a role in the generation of atherosclerotic plaques and diabetic nephropathy
MARCO (scavenger receptor family)	More restricted macrophage populations than SR-A, including alveolar, peritoneal, and thymic macrophage populations	Similar to SR-A, including silica particles	Phagocytosis of nonopsinized particles and macromolecules triggers macrophage activation and cytokine release
RNA helicases (RIG-I, Mda-5)	Cell cytoplasm	dsRNA	Bind to dsRNA produced during intracellular replication of certain classes of viruses
CRPs and serum amyloid P (Pentraxins)	Serum proteins	Bind to and affect clearance or activation of host proteins (C1q and DNA fragments) as well as constituents of some pathogenic organisms	Secreted by the liver during early acute-phase response and influence clearance and complement activation of recognized macromolecules
Peptidoglycan recognition proteins	Soluble proteins found intracellularly in leukocyte granules or synthesized by the liver and secreted into the serum	Peptidoglycan structures	Direct bacteriocidal or bacteriostatic activity by interfering with bacterial peptidoglycan wall biosynthesis
NOD-LRR receptor family (NLR) (includes NOD, NALP, CIITA, IPAF, and NAIP proteins)	Soluble intracellular proteins	NOD1 and NOD2 bind bacterial peptidoglycan; PAMPs for other proteins not identified	Survey intracellular compartment for intracellular pathogens, binding to bacterial wall fragments produced either during bacteria proliferation or lysozomal degradation; ligand binding triggers activation of NF-κB inflammation pathway
$\alpha_v\beta_{3\ (integrin)}$	Epithelial cells	*Trypanosome cruzi*	Binding induces opsonization and cell activation
CD11b/CD18 (also CR3) (integrin)	Monocytes, macrophages, and epithelial cells	LPS, constituents of *Mycobacterium tuberculosis,* yeast saccharides (including zymosan)	Binding induces opsonization and cell activation
Sialic acid–binding immunoglobulin-like lectins (Siglecs)	Surface receptors on onocytes, macrophages, NK cells, and myeloid cells	Sialylated complex carbohydrates (found on endogenous proteins and some pathogenic organisms)	Role for binding and phagocytosis of pathogenic organisms proposed

CIITA, Class II transcription activator; *CRP*, C-reactive protein; *DC*, dendritic cell; *HLA*, human leukocyte antigen; *IPAF*, ICE-protease activating factor; *LDL*, low-density lipoprotein; *LPS*, lipopolysaccharide; *MARCO*, macrophage receptor with collagenous domain; *MBL*, mannose-binding lectin; *MBP*, mannose binding protein; *NAIP*, neuronal apoptosis inhibitory protein; *NALP*, NACHT, LRR, and PYD containing proteins; *NF-κB*, nuclear factor κ-light-chain-enhancer of activated B cells; *NK*, natural killer; *NLR*, NOD-like receptor; *NOD-LRR*, nucleotide-binding oligomerization domain leucine rich repeats; *PAMPs*, pathogen-associated molecular patterns; *SR-A*, scavenger receptor type A; *TLR*, Toll-like receptor.

Table 17-3 The Cytokines

Cytokines and Cellular Targets	Examples	Biologic Consequences
	Interleukins	
Monocyte and macrophages, endothelial cells	IL-1, IL-2, IL-6, IL-10, IL-13, IL-16, TNF-α	Local inflammation, cell recruitment, hepatic acute phase reaction, sepsis response
B cells	IL-2, IL-4, IL-6, IL-7, IL-9, IL-14	Recruitment, activation, differentiation of B cells
T cells (type 1 cytokines)	IFN-α/β/γ, IL-2, IL-12, IL-15	T helper(T_H)1 response: defense against intracellular pathogens
T cells (type 2 cytokines)	IL-4, IL-5, IL-6, IL-10, IL-13	T_H2 response: defense against parasitic infections
Neutrophils, epithelial cells	IL-17, IL-22	T_H17 response: defense against extracellular pathogens; mucosal inflammation and release of anti-microbial peptides, neutrophil recruitment, and autoimmunity
	Interferons	
T cells and NK cells	IFN-α, IFN-β, IFN-γ	Upregulate activity of T cells and NK cells against virally infected cells and malignant cells
	Tissue Necrosis Factors	
All cells except erythrocytes	TNF-α, TNF-β	Pyrexia, tissue hyperemia, capillary leak, sepsis/shock syndrome, enhancement of target cell effector functions, expansion of lymphoid compartments
	Chemokines	
Monocytes and macrophages, granulocytes, dendritic cells, lymphocytes	MCPs, eotaxin, TARC, MDC, MIPs, RANTES, PF4	Recruit and activate cells of innate and adaptive immune system to specific sites of pathogen exposure, inflammation, or tissue damage
	Hematopoietic Growth Factors	
Hematopoietic cells in marrow and peripheral compartments	G-CSF, GM-CSF, M-CSF, SCF	Maintenance, growth, and differentiation of hematopoietic cells

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IFN*, interferon; *IL*, interleukin; *MCP*, macrophage/monocyte chemotactic protein; *M-CSF*, macrophage colony-stimulating factor; *MDC*, macrophage-derived chemokine; *MIP*, macrophage inflammatory protein; *PF4*, platelet factor 4; *RANTES*, regulated on activation, normally T-cell expressed and segregated chemokine; *SCF*, stem cell factor; *TARC*, thymus and activation–regulated chemokine; *TNF*, tumor necrosis factor.

Mature B cells express CD19 and CD20. Most B cells, called *B2 cells,* have a $CD5^-$ phenotype and require T-cell cooperation for function. A minority population of B cells, called *B1 cells,* expresses CD5, does not require T-cell help, and appears to function in pleural and peritoneal immunity. Given their $CD20^+CD5^+$ phenotype, B1 lymphocytes may be the population from which chronic lymphocytic leukemia arises. B cells represent approximately 10% of the lymphocytes in the BM or in circulation but account for up to 50% of the population in spleen and LNs.

After emerging from the BM compartment, T cells develop further into αβ T-cell or γδ T-cell populations. The αβ T cells are the most abundant subset and include $CD3^+CD8^+$ and $CD3^+CD4^+$ T-cell populations. $CD3^+CD8^+$ T cells, which develop into CTLs, are involved in defense against virally infected or transformed cells. $CD3^+CD4^+$ T cells can be further subdivided into T helper (TH)1 cells (stimulate development of CTLs), TH2 cells (stimulate isotype switching and antibody production in B cells), TH17 cells (induce or enhance tissue damage secondary to autoimmune or infectious processes), or T-regulatory (Treg) cells (control or limit autoimmune responses).[25-27] The γδ T cells are $CD3^+CD4^+CD8^-$ T cells that can develop in the thymus and the gut.[28] Because the γδ antigen receptor on this T-cell subset is rearranged embryonically before antigen exposure, these cells may function in innate immunity. The γδ T cells represent only 1% to 5% of circulating T cells but up to 50% of the T cells in certain epithelial sites (e.g., skin and intestinal tract), where their activity is influenced by local inflammation. Stimulatory and suppressive roles of γδ T cells' response to bacterial and viral infections and possibly malignant transformation have been demonstrated in experimental systems.

Natural killer cells are a distinct lymphocyte subset and comprise approximately 10% of the circulating lymphocyte population. NK cells are identifiable by their $CD3^-CD56^+$ phenotype. They function in defense against virally infected cells and transformed cells through the generation of cytotoxic cytokines, direct cytolytic activity, and antibody-dependent cellular cytotoxicity. Pathogen recognition is accomplished through three classes of receptors, including killer cell Ig receptors (KIRs), C-type lectins (CD94/NKG2s), and natural cytotoxicity receptors (NCRs).[29]

Monocytes, Macrophages, and Dendritic Cells

Monocytes develop in the BM and then circulate through the blood and lymphatics with an average half-life of 1 to 3 days before migrating into tissues and maturing into macrophages.[30,31] Macrophages can be found in all tissues, particularly at points of entry for pathogens such as the skin, respiratory tract, gastrointestinal tract, and genitourinary tract. Tissue-specific macrophage populations include Kupffer cells (liver), alveolar macrophages (lung), osteoclasts (bone), microglia (central nervous system), and type A lining cells (synovia), which can be identified morphologically and by surface immunophenotype.

Dendritic cells are specialized antigen-presenting cells (APCs). Similar to macrophages, DCs are found at points of pathogen entry, including the skin and mucosal surfaces, and locations of lymphocyte proliferation, such as germinal centers (GCs). DC biology is described further in Chapter 21.

Granulocytes

Granulocytes can be further subclassified into neutrophils, basophils, and eosinophils by the types of cytoplasmic granules that they contain. Neutrophils mature in the BM, where 80% to 90% of the body's store of mature neutrophils resides. The recruitment of neutrophils from the BM into the circulation and inflamed tissues can occur within hours of exposure to bacterial endotoxin. Neutrophil

effector functions include phagocytosis and cytokine production, both of which are activated through PRR-, FcR-, or CR3-dependent triggering. Neutrophils have multiple functions, including the direct killing of foreign organisms via phagocytosis or release of hydroxylases and oxidative enzymes from primary and secondary granules, release of PRRs, and the formation of neutrophil extracellular nets (webs of degraded nucleic acids and histones), which trap organisms.[32] Neutrophils (via chemokines and cytokines) also recruit and activate the cells of the adaptive immune system (lymphocytes and DCs).

The basophilic leukocytes—mast cells and basophils—have several structural and functional similarities. They are key mediators of immediate allergic and inflammatory responses, with mast cells being more predominant in tissues and basophils in circulation. Both cell types express FcεR, which induces rapid degranulation when triggered by aggregated IgE, and have granules containing histamine, platelet-activating factor, and bioactive proteoglycans. Degranulation can be rapid, producing anaphylaxis, or sustained, inducing a more sustained inflammatory response. Differences between basophils and mast cells include the expression of receptors on basophils for IgG, C3a, and C5a and receptors on mast cells for stem cell factor, interleukin-2 (IL-2), and IL-3 and in the spectrum of cytokines produced by each cell type. Basophils and diseases related to basophils are discussed in Chapter 71.

Eosinophils are found predominantly in tissues, with a smaller fraction found in circulation. The eosinophilic granules of this subset contain hydrolytic enzymes that may be damaging to invading pathogens and host tissues. Eosinophil activation also triggers leukotriene production and the release of an array of cytokines. A role in allergic responses and defense against helminth pathogens has long been presumed according to the eosinophilia characteristic of these conditions; however, the true physiologic necessity of eosinophils has yet to be demonstrated. Eosinophils may be viewed as effector cells of the adaptive immune system because they are acutely triggered by a B-cell product (IgE) and their development in part depends on T cells. Disorders of eosinophils are discussed in Chapter 70.

Non–Bone Marrow–Derived Cells Involved in Immune Function

Populations of non–BM-derived cells function in innate immunity. Renal tubular cells and epithelial cells in the gut, bronchial airways, reproductive organs, and dermis express different PRRs. In these cells, the receptors function in pathogen clearance or by triggering pathogen-dependent inflammatory responses. Bronchial airway cells secrete pulmonary surfactants and antimicrobial peptides, creating a very localized antimicrobial barrier. Liver endothelial cells use several PRRs, including the Fcγ, scavenger, and mannose receptors, to clear senescent serum proteins and pathogens. The functions of these cells dovetail with those of the leukocytes in pathogen defense and tissue homeostasis.[5,6,8,33-35]

ANATOMY OF THE IMMUNE SYSTEM

An array of soluble mediators and a repertoire of immune cells mediate the host response to microbial pathogens, to tumors, to self-antigens in autoimmunity, and to foreign antigens in graft rejections. Where do these cells and mediators come from, and where do these interactions take place?

Immune Cell Development: Primary and Secondary Lymphoid Organs

The organs and tissues of the immune system are divided into the primary *(or generative) lymphoid organs* and *secondary (or peripheral) lymphoid organs*. The *primary lymphoid organs* consist of the BM and thymus and are the sites where cells of the innate and adaptive immune system are generated and produced. The *secondary lymphoid organs* include the spleen, LNs, and epithelial and mucosa associated lymphoid tissues such as Peyer patches in the small intestine and are the sites where the adaptive immune response is generated.

Most immune cells arise in the BM. Anatomy of the BM and hematopoiesis is discussed in detail in Chapter 8. The cellular components of the innate immune response—neutrophils, eosinophils, basophils, and monocytes—leave the BM as mature, functional cells. In contrast, the cellular components of the adaptive immune response leave the BM as immature precursors that undergo further development in the thymus or secondary lymphoid organs.

T-Cell Maturation

T-cell precursors mature into functional T cells in the thymus (Fig. 17-1).[26,36,37] The thymus is composed of lymphocytes, DCs, epithelial cells, and stromal components. The thymic stroma arises primarily

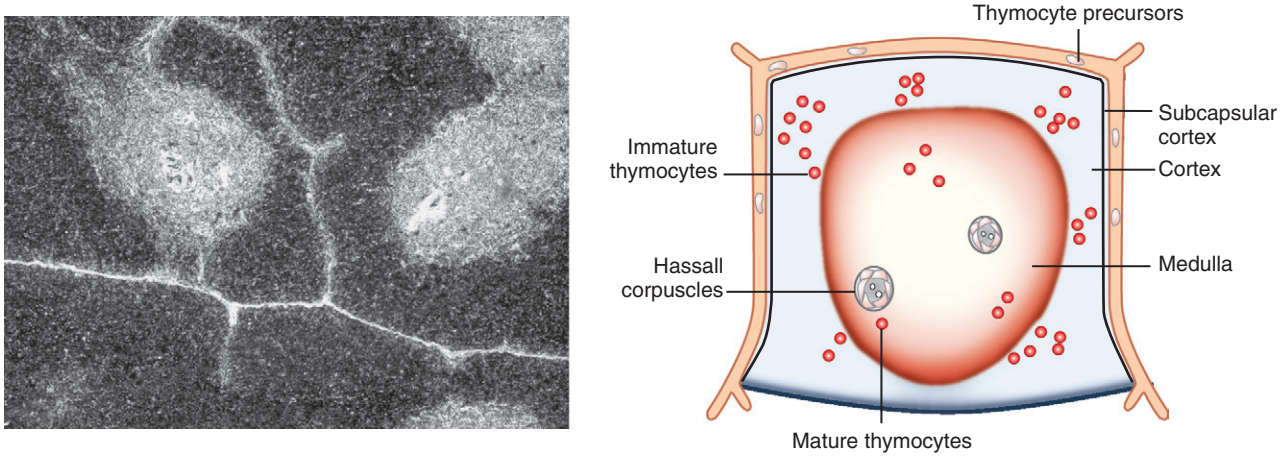

Figure 17-1 ANATOMY OF THE THYMUS. The human thymus *(left)* is composed of lobules, each separated by a thin capsule. Immediately under the capsule is a narrow zone called the *subcapsular cortex* that surrounds the larger zone of the cortex, the darkly staining region. In the center of each lobule is the medulla, the lighter staining region. In the medulla, nests of epithelial cells called *Hassall corpuscles* are visible. T-cell precursors *(right)* arising in the bone marrow migrate through the blood and enter the thymus as immature cells. During maturation in the cortex, most of the immature thymocytes fail to produce functional T-cell receptors (TCRs) and die. Cells that produce functional TCRs are positively selected to survive and migrate to the thymic medulla. Mature, naive T cells exit the medulla to the peripheral circulation.

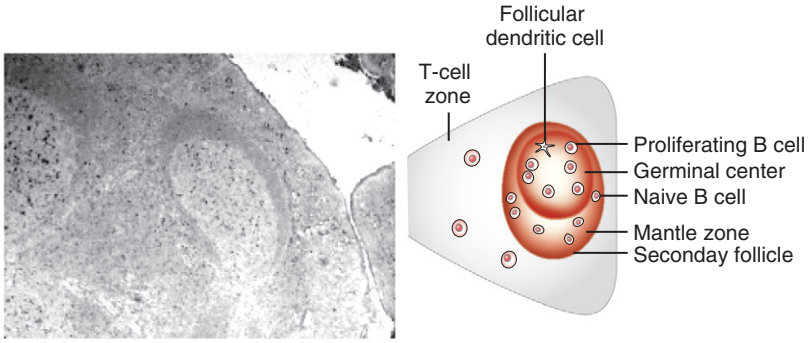

Figure 17-2 B-CELL PROLIFERATION IN LYMPH NODES. B cells primarily populate the lymphoid follicles. A section of tonsil *(left)* demonstrates a secondary follicle with a pale germinal center filled with proliferating B cells, scattered T cells, and specialized antigen-presenting cells called *follicular dendritic cells (dark staining).* The germinal center is surrounded by a darker mantle zone populated by nonproliferating B cells. Adjacent to the follicle is the T cell–rich zone of the cortex. The schematic of a section of lymph node *(right)* demonstrates a secondary follicle with a germinal center and a mantle zone. The T cells reside primarily adjacent to the follicles. However, scattered T cells can be found in the germinal center and are typically helper-T cells stimulating B-cell proliferation.

from the third and fourth pharyngeal pouches during fetal development, and the stroma is then populated with lymphocyte precursors emigrating from the BM. The stromal meshwork of the thymus, including various types of epithelial cells, is essential for thymic development. The requirement for thymic stroma in T-cell development is demonstrated in patients with DiGeorge syndrome, otherwise known as 22q11 deletion (del22q11) syndrome. These patients have deletions of one or more genes critical for fetal development, resulting in failure of involution of the third and fourth pharyngeal pouches and consequent absence of thymic stroma. Although patients with DiGeorge syndrome have T-cell precursors in the BM, they have no thymus organ and have markedly reduced numbers of mature T cells in the peripheral circulation and in tissues. As discussed in "Secondary Lymphoid Tissue," the observation that most patients with DiGeorge syndrome do have small numbers of circulating mature T cells suggests that extrathymic sites in these patients may partially substitute for the thymus in promoting T-cell maturation.

The thymus is divided histologically into two general zones, the cortex and the medulla, although these zones have microdomains thymocytes are phenotypically and functionally distinct.[37-39] Thymic precursors leave the BM, circulate in the blood, and selectively home to the thymus, entering to populate the subcapsular cortex. At this site, TCR rearrangement begins, and maturing thymocytes move to the cortex and continue to proliferate. Interactions among TCRs expressed by developing T cells and self-peptide/MHC-I complexes presented by resident thymic cortical and medullary epithelial cells (cTECs and mTECs) mediate the process known as selection.[40,41] A large fraction of thymocytes, however, fail to express a functional TCR and are never able to interact with cTECs; as a result, these cells do not receive critical survival signals from cTECs and thus die of nonselection (i.e., programmed cell death). T cells that do express a functional TCR undergo one of two fates—positive selection or negative selection. In positive selection, thymocytes that have successfully assembled a TCR with low to intermediate affinity for self-peptide–MHC complexes expressed by cTECs are selected to survive and mature. In negative selection, thymocytes bearing TCRs with a high affinity to self-peptide–MHC complexes of cTECs undergo apoptosis, resulting in the deletion of dangerous autoreactive T cells, which is proposed to reduce self-reactivity and autoimmune disease.

T cells that survive the selection process in the cortex proceed to the medulla, where they commit to a particular T-cell lineage (CD4 or CD8) and undergo further negative selection by interactions with mTECs that express tissue specific antigens promiscuously.[41-43] Negative selection by the mTECs is partially regulated by the transcription factor termed *autoimmune regulator* (AIRE). AIRE deficiency results in inadequate deletion of self reactive T lymphocytes and manifests clinically as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy in humans (APECED).[44,45]

Only 1% to 3% of the initial thymic progenitor cells succeed in surviving the selection process and thus emigrate from the thymus as non–self-reactive, functional CD4 or CD8 cells.[41,46] T-cell development is elaborated on in Chapter 19.

B-Cell Maturation

Naive B cells leave the BM and traffic to *secondary lymphoid tissues,* where the mature cells of the adaptive immune system encounter non–self-antigens and become activated. Briefly, naive cells enter primary follicles in the cortex of the secondary lymphoid tissue, such as the LN shown in Fig. 17-2.[47] When B cells in primary follicles encounter non–self-antigens that are recognized by their surface BCR/Ig, the B cells begin to proliferate and undergo somatic hypermutation (SHM) of immunoglobulin genes in an attempt to express a higher affinity BCR. B cells bearing a high-affinity BCR are positively selected to proliferate. When B-cell proliferation begins, the primary follicle becomes a secondary follicle.[48] The secondary follicle has two general regions: (1) a GC filled with the proliferating B cells, some T cells, macrophages, and DC and a (2) surrounding mantle zone of nonproliferating B cells that have not encountered an antigen they recognize. The GC can be further divided into dark and light zones, depending on the stage of proliferation, as discussed later in "Systemwide Surveillance." Chapter 18 discusses B-cell development in depth.

ENCOUNTERS WITH ANTIGEN: THE INFLAMMATORY RESPONSE

A primary function of the immune system is to protect against microbial pathogens. The most common sites for microbes to breach the protective barriers of epithelium are the skin and the respiratory, gastrointestinal, and genitourinary tracts. These tissues directly encounter the outside world and possess complex, multifaceted mechanisms for dealing with antigens.[49,50]

The local defense system is immediately activated when pathogens disrupt the epithelial barriers in these sites. These tissues are rich in components of the innate immune system, including macrophages and DCs, which perform a surveillance function in tissues. Some tissues have specialized or unique populations of macrophages and

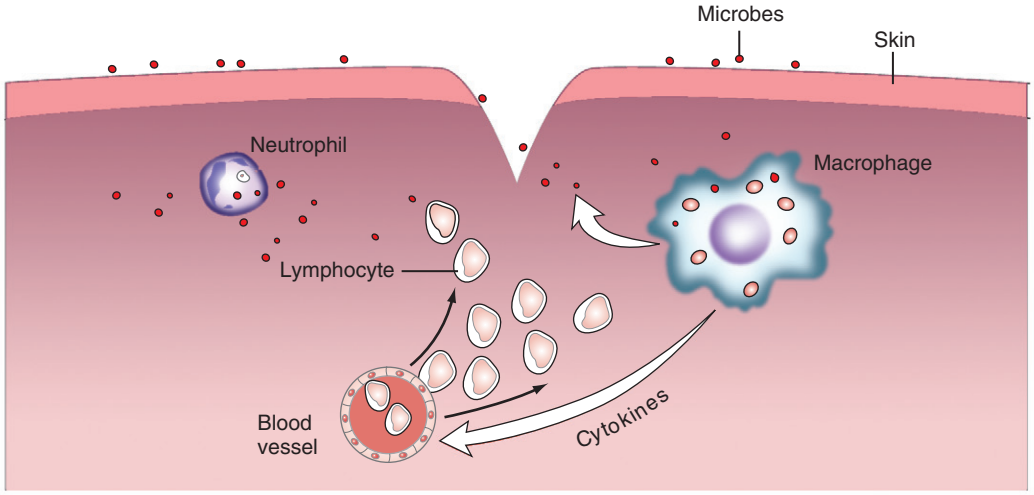

Figure 17-3 ENCOUNTERS WITH ANTIGEN. The immune system evolved primarily to protect against invading microorganisms that penetrate the epithelial coverings of the body. In this schematic, microbes entering through a break in the skin epithelium are phagocytosed by resident macrophages as the first line of defense in innate immunity. The macrophages can secrete products that are directly microbicidal as well as cytokines and other mediators that cause vasodilatation and endothelial cell separation to allow influx of soluble mediators and inflammatory cells such as neutrophils and lymphocytes into the skin. Neutrophils, as a component of innate immunity, can also directly kill microorganisms, typically by releasing granular contents. Lymphocytes responding to microbial antigens proliferate and contribute to the adaptive immune response against microbes.

DCs (see Chapter 21), although these cells have many common features in different tissues. Macrophages provide a critical first line of defense against pathogens by directly phagocytizing the microorganisms. Macrophages also send the first signals that recruit granulocytes from the circulation into the tissues (Fig. 17-3). These signals include cytokines, nitrous oxide, and leukotrienes that cause vasodilatation, endothelial cell activation, leukocyte adhesion to endothelial cells at the inflammatory site, and diapedesis of leukocytes into the tissues (see Chapter 11). The resulting exudate fluid at the site of vasodilatation is also rich in plasma proteins that participate in innate immunity, such as complement and soluble PRRs. The soluble mediators may be directly toxic to microbes or may opsonize microbes to facilitate phagocytosis and killing by granulocytes. The soluble and cellular components of the innate immune system provide the first line of defense at the tissues where pathogens invade.

The epithelial barriers also contain resident lymphocytes and plasma cells. The lymphoid cells can also respond to cytokines secreted by resident macrophages, such as IL-2, which stimulates T-cell proliferation. The ability of macrophages to secrete mediators that cause vasodilatation and recruitment of granulocytes, as well as initiate T-cell activation, illustrates the interplay between innate and adaptive immunity in tissues where antigens are encountered and underscores the point that the innate and adaptive immune systems work in concert in host defense. Resident T cells and plasma cells in the tissue can respond to antigen, with local activation of antigen-specific effector T cells and increased antibody secretion, respectively, so that the adaptive immune response is stimulated locally after pathogens are sensed by the innate immune system.

SYSTEMWIDE SURVEILLANCE: THE ROLE OF LYMPHATIC CIRCULATION

Lymphatics are an essential component of the vascular system (Fig. 17-4). Even in the absence of inflammation, a fraction of the fluid component of blood continually leaves the capillary bed during circulation because of the pressure drop between the arterial and venous sides. This fluid bathes the tissues of the body picking up antigens and cells and then drains into lymphatic channels that interdigitate in every capillary bed.

At sites of inflammation, the amount of fluid and cells draining into the local lymphatics increases because of changes in the vascular tone and permeability mediated by macrophage and neutrophil-derived chemokines, lipid mediators, and oxygen radicals. During the local inflammatory response, the exuded fluid, along with antigen-loaded DCs, T cells, and cytokines, drains from the tissues back through the lymphatic channels.

Lymphatic fluid eventually returns to blood circulation via the thoracic duct, which drains into the vena cava. However, before returning to the venous circulation, lymphatic fluid travels through the secondary lymphoid tissues and undergoes sampling for foreign antigens, thus providing a mechanism of systemic immune surveillance. The complex organization and structure of these secondary lymphoid tissues create a close interface among antigens, APCs, and lymphocytes to optimize cellular interactions to produce an efficient and robust adaptive immune response. Signals from cells within the LNs can also expand the lymphatic vessel network, again resulting in increased drainage of DCs and antigens into the LNs.[51] The movement of lymphatic fluid through secondary lymphoid tissue is an essential component of the adaptive immune system.

Lymph node anatomy is shown schematically in Fig. 17-5; the anatomy of LNs and the spleen is also discussed in Chapter 18. Fluid and cells enter the lymphatics in body tissues and gain entry to the convex surface of the LN via afferent lymphatic vessels that drain into the subcapsular sinus. Lymphatic fluid in the subcapsular sinus then courses into the trabecular sinus network that runs perpendicular to the capsule through an area called the cortex. The cortex region is composed mainly of B and T cells arranged into follicles and interfollicular zones. Follicles consist mainly of B cells, some T cells, and APCs, and interfollicular zones consist mainly of T cells and additional APCs. These zones are separate but contiguous compartments where initial B-cell and T-cell antigen encounters occur within the LN. The movement of antigen-rich fluid into these B- and T-cell zones in the cortex stimulates the proliferation of antigen-specific lymphocytes. Local B-cell proliferation in the LN further stimulates lymphatic drainage to the node.[51] In the follicles, additional processing of antigens may be carried out by local APCs, such as follicular DCs.

Follicles are functionally characterized as either primary or secondary follicles. Primary follicles are composed of nonproliferating

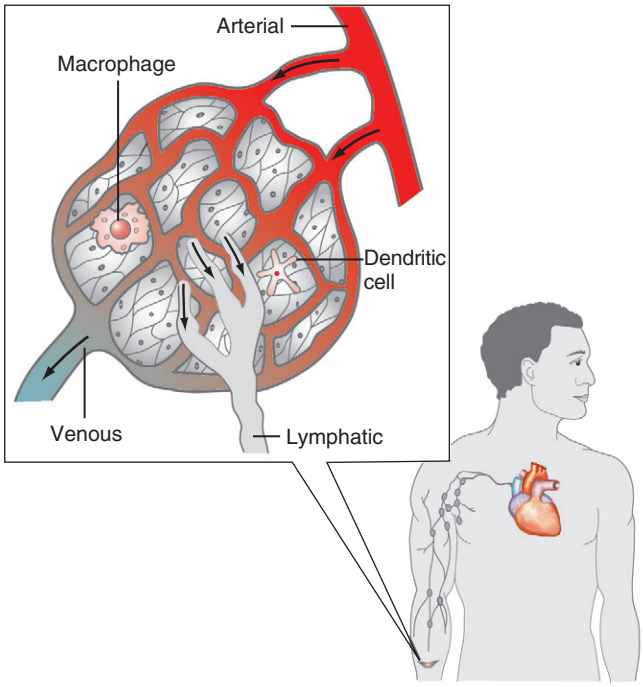

Figure 17-4 LYMPHATIC DRAINAGE IS A CRITICAL PART OF IMMUNE SURVEILLANCE. As shown in Fig. 17-3, fluid and cells leave the vasculature at sites of inflammation. Hydrostatic pressure across the capillary bed continually drives transudation of fluid from the blood into tissues. The extravasated fluid, along with antigen-presenting cells (APCs) such as macrophages and dendritic cells, collects in lymphatics *(inset)*. Lymphatics drain past series of lymph nodes *(dark ovals),* affording the APCs the opportunity to migrate to lymph nodes and stimulate lymphocytes in the nodes. Fluid in lymphatics passing through chains of lymph nodes eventually collects in the thoracic duct, which returns the fluid to the vascular circulation by draining into the vena cava.

naive B cells that have yet to encounter antigen recognized by their surface BCR/Ig complex. B-cell recognition of an antigen displayed by a Th cell or other APC results in activation and clonal expansion. A fraction of these activated proliferating B cells form GCs, which are surrounded by a mantle zone of naive B cells, which together comprise a secondary follicle.

Germinal centers are classically divided into two compartments, denoted as the dark and light zone based on their appearance under light microscopy.[52,53] Dark zones contain a high density of proliferating B cells termed *centroblasts,* which do not express surface immunoglobulin (sIg) and are located adjacent to T-cell areas.[53] The light zone are termed such, as they appear less opaque because of the reduction in cellular density secondary to the presence of an extensive loose network of follicular DCs (FDCs).[54,55] B cells in the light zone are termed *centrocytes,* which in contrast to the centroblasts, are small, nondividing B cells expressing sIg. Some of these cell types, such as centrocytes and centroblasts, are discussed in Chapter 72 in the context of lymphoid malignancies.

The GC reactions, colloquially known as the B-cell selection process, are viewed as a series of sequential events within the dark and light zone where B cells undergo cyclic shuttling and reentry to and from these two zones. The cyclic reentry model proposes that centroblasts in the dark zone undergo cell division and SHM of variable light chain genes mediated by the enzyme activation-induced cytosine deaminase (AID).[56] Next they reexpress BCR/sIg and exit the cell cycle, migrating into the light zone to interact with antigen-presenting FDCs. In light zones, B cells with increased affinity for antigen are preferentially selected for survival receiving vital signals from T follicular helper cells; in contrast, B cells with impaired or absent antigen binding undergo apoptosis and clearance by resident macrophages.[53,57] Selected centrocytes in the light zone are thought to return to the dark zone to undergo further rounds of proliferation, affinity maturation, and selection to improve the affinity of B-cell repertoire.[54] Positively selected GC B cells eventually leave the GC, differentiating into memory B cells or plasma cells possessing somatically mutated immunoglobulin genes that encode for a high-affinity BCR/Ig.[53] The genetically modified capability of B cells to generate a fast, highly specific humoral immune response upon a second encounter with the same pathogen forms the mechanistic basis of humoral memory.[52,53,55,57,58] Memory B cells may circulate through secondary lymphoid organs and colonize the splenic marginal zone. Plasma cells take residence in the BM and spleen for a long period of time.[59]

The lymphatic fluid within the cortical trabecular sinus network continues to drain toward the medullary sinus, which lies deep to the cortex, forming the central part of the LN, known as the *hilum*. The medullary sinus contains additional APCs, some T cells, and numerous plasma cells that have migrated from the cortex to the medulla. There, plasma cells may leave the LN in the lymphatic fluid via the efferent lymphatic vessel at the hilum, to traffic to peripheral tissue such as the BM. Lymphatic fluid travels through additional LNs on the way to the thoracic duct; thus, antigens and cells draining from sites of inflammation travel through chains of LNs. In the lymphatic system, trace amounts of microbial proteins or toxins, together with activated monocytes, macrophages, DCs, lymphocytes, and the cytokines produced (the direct consequence of PAMP–PRR ligation), are kept in anatomic proximity, providing numerous opportunities for the antigens to encounter antigen-specific lymphocytes and stimulate the adaptive immune response.

In addition to lymphatic fluid, blood must also travel through LNs to provide oxygen and nutrients and to deliver new B and T cells to the tissue. Although lymphatic fluid contains lymphocytes from tissues that have already encountered antigens, lymphocytes in blood are predominantly naive T cells that have emigrated from the thymus but have not yet encountered antigens. Arterial blood enters the LN at the hilum, where arterioles arborize toward each follicle. Naive T cells leave the blood to enter LNs through specialized vessels called *postcapillary venules,* which arise from follicular capillary beds, and travel through the T-cell–rich interfollicular zones.[55] Naive T cells exit from postcapillary venules into the T-cell zone, and if the naive T cells encounter antigens they recognize, the cells remain in the node to proliferate and differentiate. If the naive T cells do not encounter antigens they recognize, the cells drain by means of lymphatic fluid back to the blood and continue the circular route from the blood through LNs to lymphatics and back to blood (refer to Chapter 18 for further information on T-cell immunity).

Egress of lymphocytes from LNs and from the thymus is regulated by a specialized lipid produced in lymphoid tissue known as sphingosine-1-phosphate (S1P). Lymphocytes express S1P receptor-1 ($S1P_1$) receptors that facilitate their egress from tissues into blood. Novel immunosuppressive therapeutics are being developed that are S1P antagonists; these S1P antagonists reduce release of lymphocytes from lymphoid tissues into blood.

SECONDARY LYMPHOID TISSUE: COMMON AND UNIQUE ANATOMY AND FUNCTIONS

The spleen is an important site for B-cell development and for antigen presentation and stimulation of the adaptive immune system.[60-62] Lacking afferent lymphatics, the spleen serves to sample blood for foreign antigens (rather than lymphatic fluid), which gains access via the splenic artery. The spleen is divided into two functionally and morphologically distinct compartments, the white pulp and the red pulp. The white pulp is composed mainly of lymphoid cells and is the site of antigen detection and presentation to splenic B and T cells. The red pulp consists mainly of myeloid cells, including macrophages that ingest opsonized antigens and damaged erythrocytes from the systemic circulation. The red pulp functions also as a site of extramedullary hematopoiesis early in fetal life and is a storage

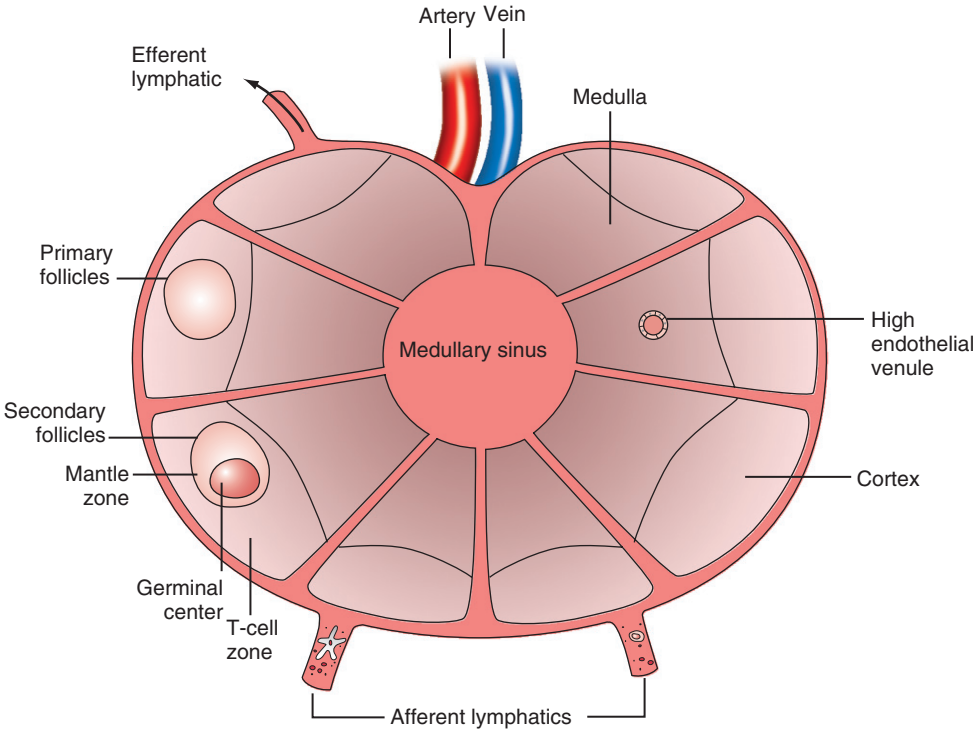

Figure 17-5 LYMPH NODE ANATOMY. The lymph node is surrounded by a capsule. Afferent lymphatics draining tissues enter the node on the convex side into the capsule. Fluid and cells drain through the node and collect in the medullary sinus, where the fluid leaves the node through efferent lymphatics to rejoin the lymphatic circulation. The outer rim of the node is called the *cortex* and contains primary follicles composed of naive, nonproliferating B cells that have not encountered antigens and secondary follicles with proliferating B cells in the germinal center. The germinal center can be subdivided into dark and light zones. Each lymph node is supplied with blood by the arterial circulation. Arterioles expand into a meshwork of capillaries within each follicle, and venous blood drains back out of the node. Naive T cells in the peripheral circulation can exit the blood and enter the lymph node through the high endothelial venules.

site for iron, erythrocytes, and platelets. Extramedullary hematopoiesis in the spleen may also occur postnatally in patients with diseases in which the BM is not competent to support hematopoietic cell development.

In many mammalian species, including humans, splenic blood flows through a unique vascular circulation that ensures the interposing of blood (and therefore bloodborne antigens) with the lymphoid areas of the white pulp. This has been best characterized in the murine model.[61,62] In this model, the splenic white pulp consists of three compartments—the periarteriolar lymphoid sheath (PALS), follicles, and the marginal zone—that interact with blood through an open sinusoidal arterial network.[61,63] The PALS is the spleen's T-cell zone and is found surrounding the central artery. Follicles in the spleen are found adjacent to the PALS and are capable of generating primary and secondary follicles with GCs as in LNs. The marginal zone, composed of subsets of B cells and macrophages, surrounds the follicles in the spleen and serves as the major route of entry of bloodborne antigens and lymphocytes from the blood into the white pulp. Unlike other organs that have a closed vascular circulation in which blood travels from arterial to venous circulation through capillary beds, branches of the splenic artery penetrate the white pulp, forming an open sinusoidal network termed the *marginal sinuses*.[63,64] From the marginal sinuses, blood filters through the white pulp regions of the spleen to be sampled by resident B and T lymphocytes. The spleen does have efferent lymphatics, and fluid and cells that do not exit through the splenic vein collect by means of lymphatics that originate in the white pulp and drain into the lymphatic circulation. Beyond the white pulp, the splenic artery sends additional branches into the red pulp for further blood antigen surveillance and filtration that is accomplished by macrophages.

In addition to LNs and the spleen, there are numerous other sites of secondary lymphoid tissue.[65] A critical part of the secondary lymphoid system is the mucosa-associated lymphatic tissue (MALT). As the name implies, the MALT is in physical proximity with the mucosa (i.e., the epithelium and associated connective tissue that line the surfaces of the body). MALT is found at sites where antigens most commonly breach these epithelial barriers: the gastrointestinal, respiratory, and genitourinary tracts. In some tissues, the MALT forms relatively large structures that can be clearly distinguished histologically, such as the Peyer patches in the ileum and in the lymphoid tissue under the epithelium of the appendix. In these sites, perhaps because of the constant stimulation by microbial pathogens in the intestine, the MALT resembles lymphatic tissue in the spleen and LNs, with well-demarcated primary and secondary follicles that contain primarily B cells and intervening T-cell rich zones.

In other tissues, such as the genitourinary tract and the salivary glands, the microscopic anatomy of the MALT may not be as well defined as seen in Peyer patches; but the stromal tissue underlying the epithelium contains numerous lymphocytes and APCs. These sites provide an additional compartment of secondary lymphoid tissue where antigens can accumulate, be processed, and be presented to lymphocytes to stimulate an adaptive immune response.

In addition to serving as part of the secondary lymphoid tissue, the MALT may also provide an alternative site of primary lymphoid tissue for T-cell development.[66] In support of this theory, it has been observed that children with DiGeorge syndrome, in whom the thymus does not develop, do have some circulating mature T cells, although the number of T cells is greatly reduced. This suggests that the T-cell precursors emigrating from the BM can mature in other sites, such as the intestine, if the thymus is absent.

Whereas the MALT constitutes a lymphoid population beneath the surface epithelium, a separate population of lymphocytes, primarily T cells, traffics directly through the epithelium in certain tissues, such as the gastrointestinal tract, on surveillance for pathogens. These intraepithelial lymphocytes (IELs) include αβ T-cells and γδ T-cells, and comprise 1 in every 5 to 10 cells in the intestinal epithelium. Because the lining of the intestine is the largest organ surface area of the body, IELs are one of the largest T-cell populations. These IEL T-cells are composed of different subpopulations, some of which are conventional T cells that recognize foreign antigens; others are regulatory T cells that limit the extent of an immune response and maintain immune homeostasis, a critical function in the antigen-rich milieu of the gut.[34,50]

CHAPTER 18

B-CELL DEVELOPMENT

Kenneth Dorshkind and David J. Rawlings

B cells are the subset of lymphocytes specialized to synthesize and secrete immunoglobulin (Ig). Their name derives from the finding, made in the mid-1950s, that removal of the avian *b*ursa of Fabricius severely compromises antibody production. In contrast to birds, B-cell production in mammals occurs in the bone marrow (BM) during postnatal life. The generation of B cells in that tissue is referred to as *primary* B-cell production.

B lymphocytes, similar to all blood cells, are derived from hematopoietic stem cells (HSCs). HSCs generate B–cell–specified progenitors that mature through a series of defined stages into surface Ig–expressing B lymphocytes. These newly generated B lymphocytes then migrate into *secondary* lymphoid organs, the spleen in particular, where they undergo final maturation. At this point, the mature B cells may remain in the spleen or relocate via the circulation to additional tissues such as lymph nodes, where they are poised to respond to antigenic challenge.

The aim of this chapter is to summarize B-cell development in primary and secondary lymphoid tissues. The discussion focuses initially on primary B-cell development in the BM and the regulation of that process by local and systemic signals. The final sections of the chapter outline B-cell maturation in secondary lymphoid tissues. The information presented provides a basis for understanding abnormalities of B-cell development, such as leukemia, lymphoma, and immunodeficiency states that are discussed in other chapters. Studies in mice have contributed much to what is known about B-cell development and have served as a basis for understanding human B lymphopoiesis. Thus, although we emphasize the human literature as much as possible, frequent reference to findings in mice are made.

THE HEMATOPOIETIC HIERARCHY AND STAGES OF B-CELL DEVELOPMENT

B lymphocytes, similar to all hematopoietic cells, are derived from HSCs that can sustain long-term, multilineage blood cell production for the lifetime of the organism.[1] HSCs are able to function in this capacity because they can self-renew, thereby producing additional stem cells, as well as generate lineage committed progenitors from which mature myeloid and lymphoid cells derive (Fig. 18-1).

Advances in the development of monoclonal antibodies to leukocyte cell surface antigens and in flow cytometry have made it possible to isolate murine and human B lineage progenitors at various stages of development. For example, a cell termed the *common lymphoid progenitor* (CLP) is one of the earliest B-cell progenitors. Murine CLPs can be resolved by their lineage–negative (Lin^-) c-kit^{low} Sca-1^{low} interleukin-7 (IL-7) receptor-positive (IL-$7R^+$) phenotype while human CLPs are $CD34^+$, $CD45RA^+$, $CD7^+$, $CD10^+$ IL-$7R^+$ cells.[2,3] Lin^- indicates that the cells lack expression of determinants present on mature myeloid, erythroid, and lymphoid lineage cells. Many schemes of hematopoiesis indicate that the CLP is the precursor from which all T and B cells arise. However, an emerging view based on murine studies is that CLPs are primarily destined to generate B lymphocytes.[2]

The stages of B-cell development between the CLP and IgM^+ B cells are well defined in both mice and humans. The earliest B-lineage progenitor in both species is termed the *pro-B cell*. Ig heavy chain gene rearrangements have initiated in these cells, and if the rearrangement is successful, an Ig heavy chain of the μ class is expressed in the cytoplasm. At this stage, the cells are defined as *pre-B cells*. Finally, after light chain gene rearrangements have occurred and light chain protein is expressed, pre-B cells mature into B lymphocytes that express the assembled Ig molecule on their surface. The designation of a cell as a B lymphocyte should be restricted to cells that express surface Ig.

The phenotypic subdivision of cells within the pro-, pre- and B-cell compartments based on the differential expression of cell surface antigens is possible as shown in Fig. 18-1.[2] For example, human pro-B cells can be resolved based on their expression of CD10, CD34, and CD19. After an Ig heavy chain gene has undergone productive rearrangement and is expressed, μ heavy chain protein is detected in the cytoplasm of pre-B cells that no longer express CD34. Finally, productive rearrangement and expression of an Ig light chain gene result in maturation of pre-B cells into surface IgM expressing B-cells.[3] Developing and mature B-lineage cells also express additional cell surface determinants, which include CD20, CD21, CD22, CD24, CD38, and CD40, several of which are linked to critical intracellular signaling pathways. Antibodies against the CD20 determinant (Rituximab) are in widespread clinical use for the treatment of lymphoma and, increasingly, autoimmune diseases.

TRANSCRIPTIONAL REGULATION OF B-CELL DEVELOPMENT

The ability to resolve specific stages of B-cell differentiation has made it possible to determine when the expression of transcription factors critical for B-cell development occurs. These observations, combined with the analysis of genetically engineered strains of mice in which the genes encoding specific transcription factors have been deleted, have made it possible to obtain a sophisticated understanding of the transcriptional regulation of B-cell development.[4]

Early blood cell development is dependent on PU.1, an Ets family member. Mice in which PU.1 is not expressed produce erythroid and megakaryocytic but not monocytic, granulocytic, and lymphoid cells. As a result of this severe defect, *PU.1* knock-out mice die during embryonic development. The developmental potential of hematopoietic cells is specified toward a lymphoid fate by products of the *Ikaros* gene. Ikaros is an interesting transcription factor because rather than activating gene expression, it acts as a repressor by associating with transcriptionally silent genes in foci containing heterochromatin.

Further specification toward the B-cell lineage is dependent on expression of additional transcription factors that include early B-cell factor (EBF) and the *E2A*-encoded splice variants E12 and E47. Each of these DNA-binding proteins regulates the expression of a variety of B-lineage target genes and induces expression of additional transcription factors that play a role in B-cell development. That EBF and E2A expression play a critical role in B lymphopoiesis has been demonstrated by the fact that mice in which they are not expressed exhibit an almost complete block in B-cell development at the pro-B-cell stage.

Early B-cell factor– and E2A-expressing progenitors can still exhibit some non-B lineage potential, indicating that the expression

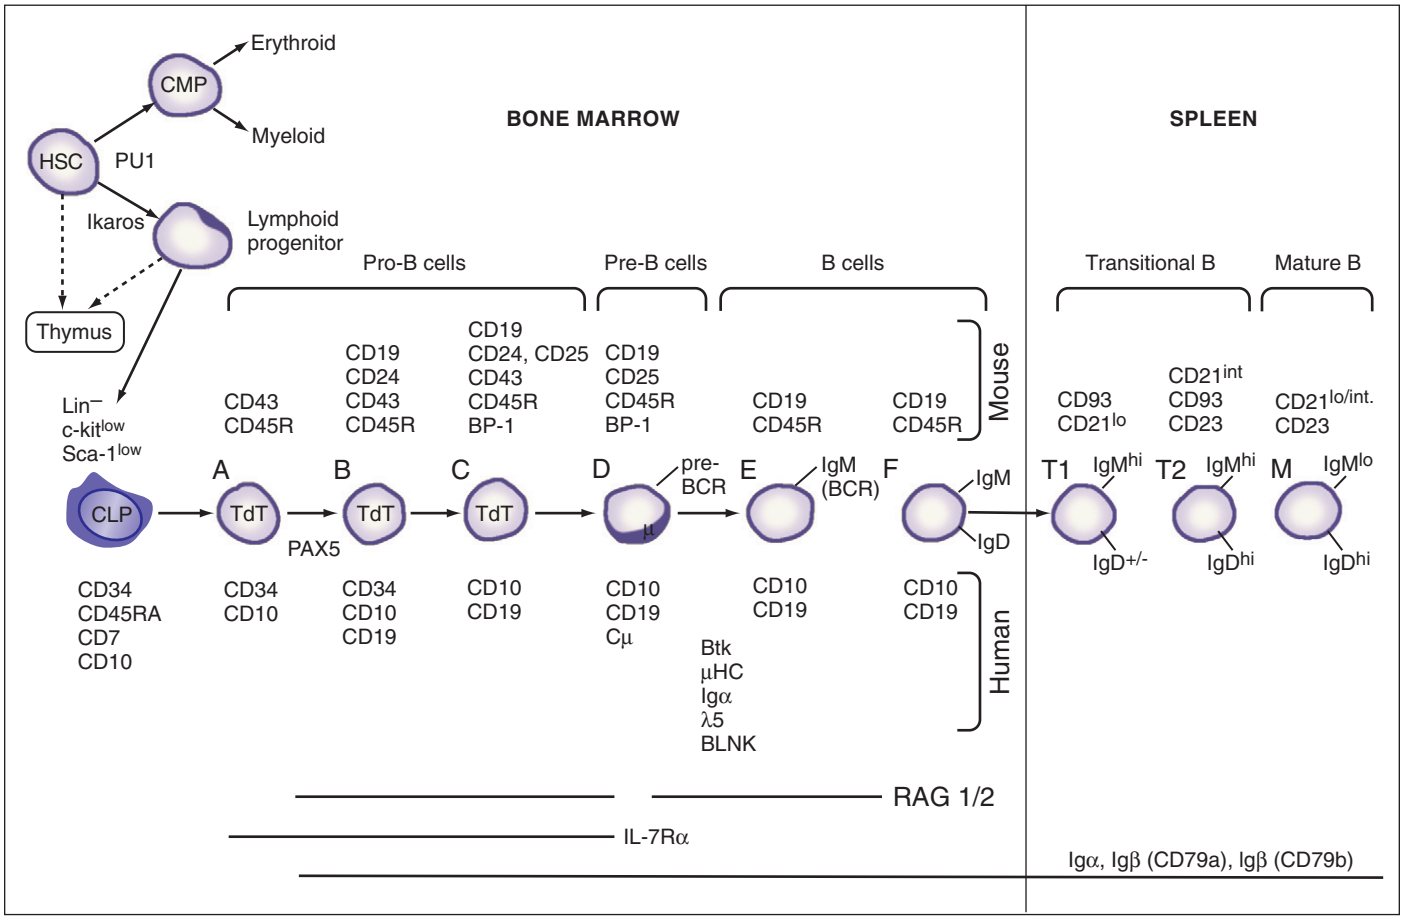

Figure 18-1 HEMATOPOIESIS WITH AN EMPHASIS ON B-CELL DEVELOPMENT. Stages of human and murine B-cell development and selected cell surface, cytoplasmic, and nuclear determinants expressed at various stages of differentiation are shown. The *dashed lines* leading to the thymus indicate that the precise identity of the bone marrow (BM)–derived, thymus-seeding cells is unclear. After leaving the BM, newly produced B cells migrate to the spleen and mature through transitional cell stages into marginal zone or follicular B cells. The phenotype of mature B cells refers to the latter population. *CLP,* common lymphoid progenitor; *CMP,* common myeloid progenitor; *HSC,* hematopoietic stem cell; *Ig,* immunoglobulin; *M,* mature, naïve B cells; *RAG,* recombinase-activating gene; *T1,* transitional 1 B cells; *T2,* transitional 2 B cells.

of these DNA binding proteins does not result in absolute commitment of cells to the B lineage. Instead, this is dependent on expression of the Pax5 transcription factor. Phenotypically identifiable B-cell precursors are present in *Pax5* knock-out mice, and when placed under appropriate conditions, they can differentiate into myeloid, T, and natural killer (NK) cells. However, if the gene encoding Pax5 is introduced into Pax5-deficient precursors, this developmental promiscuity is no longer observed. Thus, a critical function of Pax5 is to suppress non–B lineage potential.[5] One way in which this is accomplished is by extinguishing expression of myeloid growth factor receptors, such as those for macrophage colony-stimulating factor. Pax5 also may inhibit the T-cell potential of lymphoid-restricted progenitors by antagonizing expression of Notch1, a cell-surface receptor whose stimulation activates signaling pathways required for commitment to the T-cell lineage. In addition to regulating commitment to the B-cell lineage, continued Pax5 expression is necessary to maintain lineage fidelity even in relatively mature B cells.

DEVELOPMENTAL CHECKPOINTS DURING B-CELL DIFFERENTIATION

As cells mature from pro-B cells into B lymphocytes, they pass through two critical checkpoints. The first occurs at the pro-B to pre-B-cell transition and is dependent on successful recombination of the Ig heavy chain gene and expression of Ig heavy chain protein. The second occurs at the pre-B to B-cell transition, where signaling through the pre-B-cell receptor (pre-BCR [B-cell receptor]) leads to expression of light chain protein and surface expression of the mature BCR.[6] The events that must occur at each of these checkpoints for a B-cell progenitor to survive and mature are discussed in the following sections.

THE PRO-B TO PRE-B CELL TRANSITION

The expression of Ig heavy chain protein is dependent on the functional rearrangement of an Ig heavy chain gene.[7] If this occurs successfully, Ig heavy chain protein of the μ class is expressed in the cytoplasm of pre-B cells.

The genes that encode Ig heavy chain protein are located on human chromosome 14 (Fig. 18-2). The heavy chain gene consists of distinct variable (V), diversity (D), joining (J), and constant (C) regions. The V region genes are located at the 5′ end of the Ig heavy chain locus, and each consists of approximately 300 base pairs. These genes, which are separated by short intron sequences, are organized into seven families based on sequence homology. There are about 25 human D region genes located 3′ to the V region. These also are grouped into families, and at least 10 have been described. Downstream of the D region are six human J region genes. Finally, 10 C region genes representing alternative Ig isotypes are arranged in tandem.

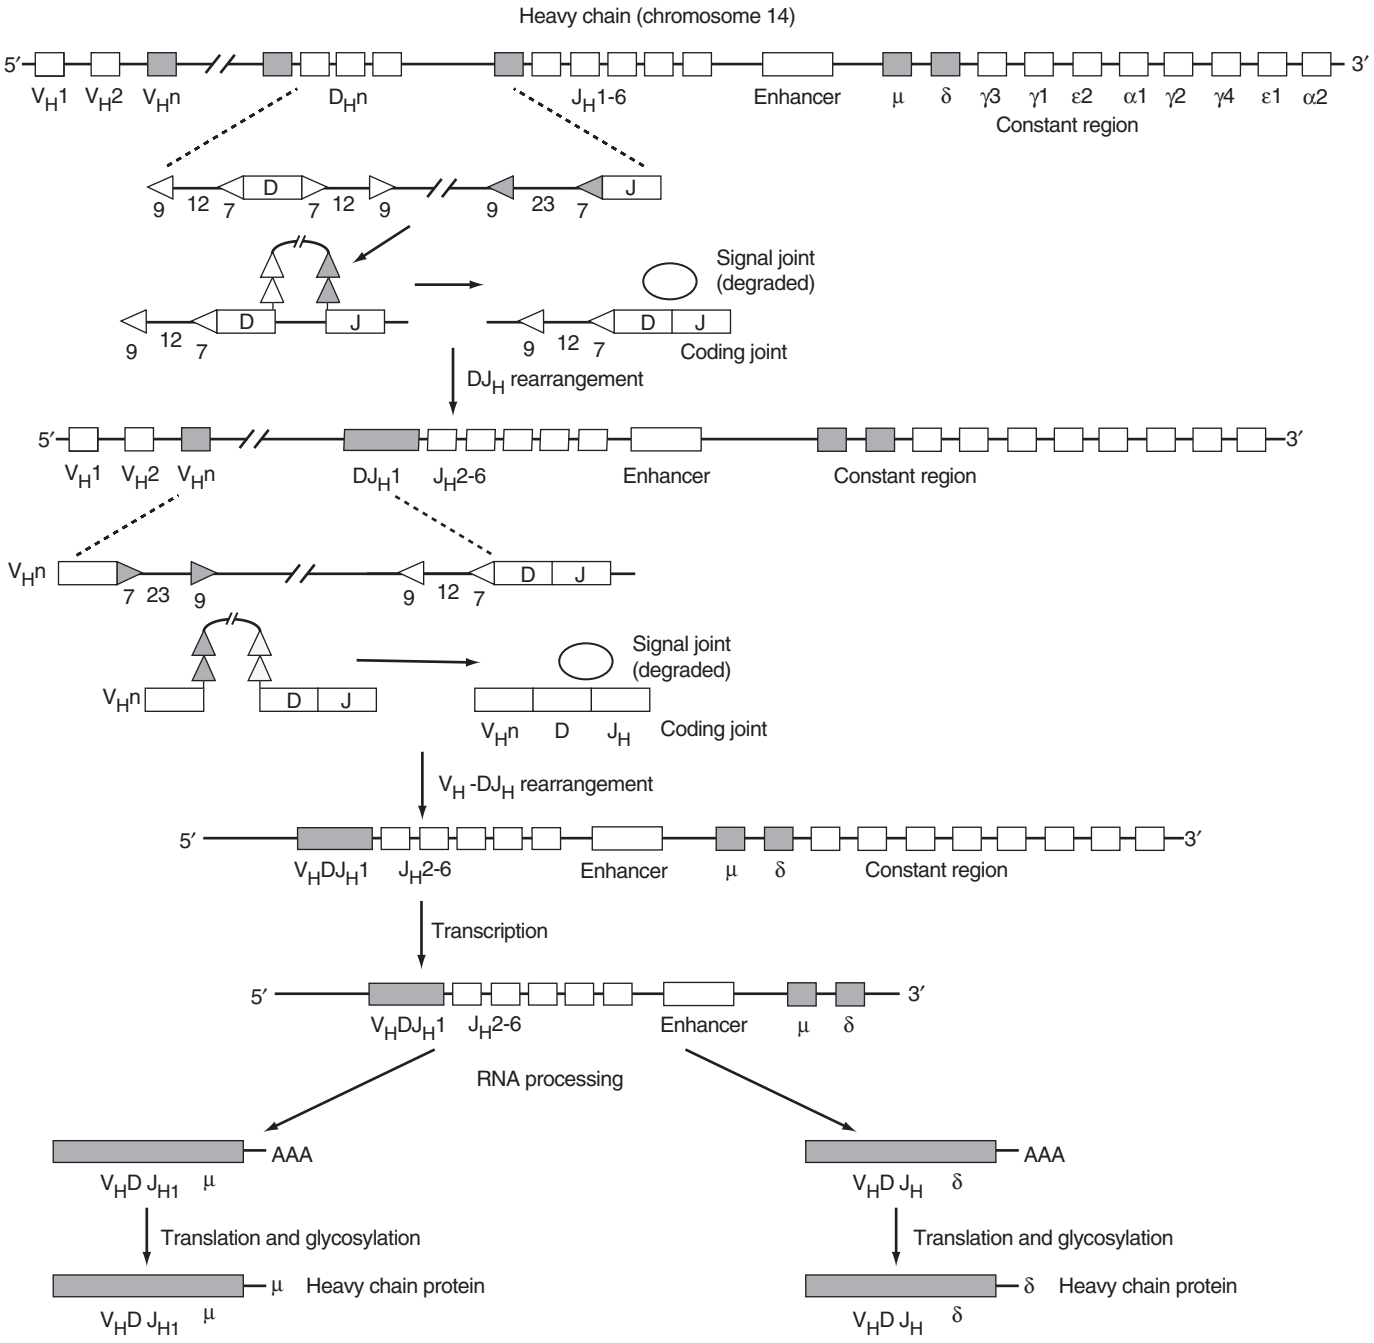

Figure 18-2 REARRANGEMENT AND EXPRESSION OF THE HUMAN IMMUNOGLOBULIN HEAVY CHAIN GENE. The figure shows the Ig heavy chain gene and the signal sequences 3′ of each V region locus, 5′ and 3′ of each D region locus, and 5′ of each J region locus. These consist of heptamer and nonamer sequences separated by either 12 or 23 base pairs. During immunoglobulin (Ig) recombination, a signal sequence of 12 base pairs can only join to another of 23 base pairs (the so-called 12-23 rule). As shown in the figure, initial heavy chain gene rearrangements form coding joints between D and J regions as well as signal joints that are ultimately degraded. Subsequently, the joining of the V region gene to the DJ complex occurs. After a successful rearrangement, the VDJ complex, the μ intron, and portions of the constant regions are transcribed. RNA processing and differential splicing results in formation of an mRNA molecule that is then translated. In the example shown, the rearranged VDJ complex and the constant region, with the μ and δ C region genes, is transcribed. After RNA processing and translation, a particular B cell could then express μ protein, δ protein, or both.

Sterile Transcripts

Ig heavy chain gene rearrangement is preceded by transcription of the unrearranged heavy chain locus. This results in the production of developmentally regulated transcripts of unrearranged Ig genes, referred to as *germline* or *sterile transcripts*. Multiple species of sterile transcripts have been described, and some could conceivably encode proteins. A mechanistic link between transcription and Ig gene rearrangement has been hypothesized. For example, transcription might make unrearranged Ig genes accessible to both RNA polymerase and V(D)J recombinase, the germline transcripts could function in the rearrangement reaction, or transcription could alter structural characteristics of DNA, making the recombination signal sequences (see later) better targets for recombination.

Immunoglobulin Heavy Chain Gene Rearrangement and Expression

Subsequent to the appearance of sterile transcripts, Ig heavy chain gene rearrangements occur. Because the coding regions of the V, D, and J region segments are separated from one another, their juxtaposition with deletion of the intervening intron must occur. The initial event during heavy chain gene rearrangement juxtaposes a D region segment to a JH segment. Although in theory any D region gene can join with equal frequency to any one JH region gene, there may be preferential utilization of selected D and JH region genes at various times during fetal and adult B-cell development. After successful D–JH recombination, a VH region gene rearranges to the D–JH complex. Evidence suggests that biased usage of JH proximal VH genes occurs in the newly generated repertoire of neonatal mice and humans. The heavy chain C region remains separated from the rearranged VHDJH complex by an intron, and this entire sequence is transcribed. RNA processing subsequently leads to deletion of the intron between the VHDJH complex and the most proximal C region genes. After translation, μ heavy chain protein is expressed in the cytoplasm of pre-B cells.

The process just described is dependent on an enzymatic machinery that deletes intronic sequences and joins coding segments of DNA. The enzymes that mediate these functions act through recognition of recombination signal sequences that are located 3′ of each heavy chain V region exon, 5′ of each heavy chain J segment, and 5′ and 3′ of each heavy chain D region gene. Fig. 18-2 shows the association of these recognition sequences with the various heavy chain exons. Each recombination signal sequence consists of conserved heptamer and nonamer sequences separated by nonconserved DNA segments of 12 or 23 base pairs. During Ig gene recombination, these recognition sequences form loops of DNA, which in turn bring the coding exons in apposition to one another. These noncoding loops are subsequently deleted and degraded.

The expression of two highly conserved proteins, referred to as recombinase-activating genes-1 (RAG-1) and RAG-2, is required for heavy and light chain gene recombination.[8] Mice and humans in whom RAG genes are not expressed do not generate B or T cells. Results from cell-free systems that measure V(D)J recombination indicate that RAG proteins are involved in cleavage of DNA at recombination signal sequences and the subsequent joining of coding sequences to one another. In addition to the RAG proteins, general DNA repair enzymes, those encoded by the Ku complex of genes in particular, also play a critical role in Ig heavy chain gene recombination.

After the productive rearrangement of at least one heavy chain gene, transcription of the rearranged locus occurs. Transcription is dependent on the binding of various transcription factors to specific promoter sequences located 5′ of each heavy chain V region and one or more heavy chain enhancer regions located 3′ of the J region genes and downstream from the CH region genes (see Fig. 18-2). Many of the transcription factors that bind within these sites have been identified. These include the previously described E12 and E47 proteins encoded by the *E2A* gene. Before Ig gene rearrangement, E12 and E47 proteins may be in an inactive state owing to their heterodimeric association with another protein known as Id. In this configuration, DNA binding by E12 and E47 does not occur. Thus, successful transition from the pro-B to pre-B-cell stage is dependent on cessation of Id expression. This conclusion is consistent with the fact that mice expressing an Id transgene have a complete block in B-cell differentiation.

Allelic Exclusion

Each pro-B cell has two Ig heavy chain genes, but only one of these encodes μ protein in any given cell. This phenomenon is known as *allelic exclusion*. One theory for how this occurs is that functional Ig rearrangements are rare, so the chance that two functional rearrangements will occur in an individual cell is extremely low. An increasingly accepted, second model of allelic exclusion is that the expression of μ protein from a successfully rearranged allele inhibits rearrangements at the other heavy chain allele. As discussed subsequently, these signals may be mediated through the pre-BCR complex. However, if rearrangements are unsuccessful at one heavy chain locus during B-cell development, recombination will initiate at the second one. If productive, these cells will then mature into pre-B cells. If this rearrangement is also defective, cells will undergo apoptosis.

Expression of the Pre-B Cell Receptor

When μ heavy chain protein is first synthesized, it associates with a chaperone protein known as binding immunoglobulin protein (Bip) in the endoplasmic reticulum. However, it subsequently appears on the cell surface with the *surrogate light chains,* encoded by genes located on chromosome 16 in mice and on chromosome 22 in humans, that together function in a manner analogous to that identified for conventional light chains. The surrogate light chain proteins, referred to as Vpre-B and λ5, are noncovalently linked to one another.[9] λ5 in turn is covalently linked to the CH1 domain of the μ heavy chain via a carboxyl-terminal (C-terminal) cysteine. This μ heavy chain–surrogate light chain complex is associated with two additional transmembrane proteins, Igα and Igβ, and the entire complex is referred to as the pre-BCR. The intracellular tails of both Igα and Igβ contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function of the pre-BCR (Fig. 18-3, *upper panel*).

One role of the surrogate light chains is to select heavy chains that will ultimately be capable of pairing with conventional light chains. In fact, pre-B cells that pair with surrogate light chains to form the pre-BCR have a significant proliferative advantage, thus ensuring that their numbers will increase and they will generate progeny that will contribute to the B-cell repertoire. Another function, as described previously, may be to mediate allelic exclusion. As soon as the pre-BCR is expressed, the genes encoding RAG-1 and RAG-2 are turned off, and the previously synthesized proteins are degraded. This effectively halts further Ig heavy chain gene rearrangements.

Lipid rafts that contain mediators of intracellular signaling such as Lyn are constitutively associated with the pre-BCR in human pre-B cells.[10] Cross-linking of the pre-BCR leads to an increase in Lyn kinase activity; phosphorylation of the Igβ chain; and recruitment and activation within the pre-BCR complex of additional signaling intermediates, including spleen tyrosine kinase (Syk), B cell linker protein (BLNK), phosphoinositide-3 kinase (PI3K), Bruton's tyrosine kinase (Btk), VAV, and phospholipase C-γ (PLCγ2). These events lead to calcium flux and activation of signaling cascades within the pre-B cell. Pre-B cells in which signaling through the pre-BCR occurs have a marked growth advantage over pre-B cells that do not express a pre-BCR. A logical assumption is that these events are initiated by binding of the extracellular portion of the pre-BCR to an environmental ligand, but no definitive pre-BCR ligand has been identified to date. Thus, precisely how these signaling events are initiated in the absence of external cross-linking ligand remains unclear, although it appears likely that constitutive signaling after pre-BCR surface expression may be sufficient. Recent structural studies suggest that the pre-BCR constitutively assembles as an oligomer providing a potential mechanism for this behavior.[11]

These signaling pathways are crucial in developing pre-B cells. One of the best examples of this requirement is the prototypical humoral immunodeficiency, X-linked agammaglobulinemia (XLA), first described in 1952 by Bruton. XLA results from mutations within the gene segments that encode the nonreceptor tyrosine kinase, Btk. In males who express a defective Btk protein, pre-B-cell clonal expansion is markedly depressed, and there is an almost complete loss of immature B cells in the BM and in secondary lymphoid organs. As a result, affected males develop recurrent bacterial infections early in life because of a profound decrease in circulating Ig. A nearly identical clinical phenotype also has been observed in persons with mutations

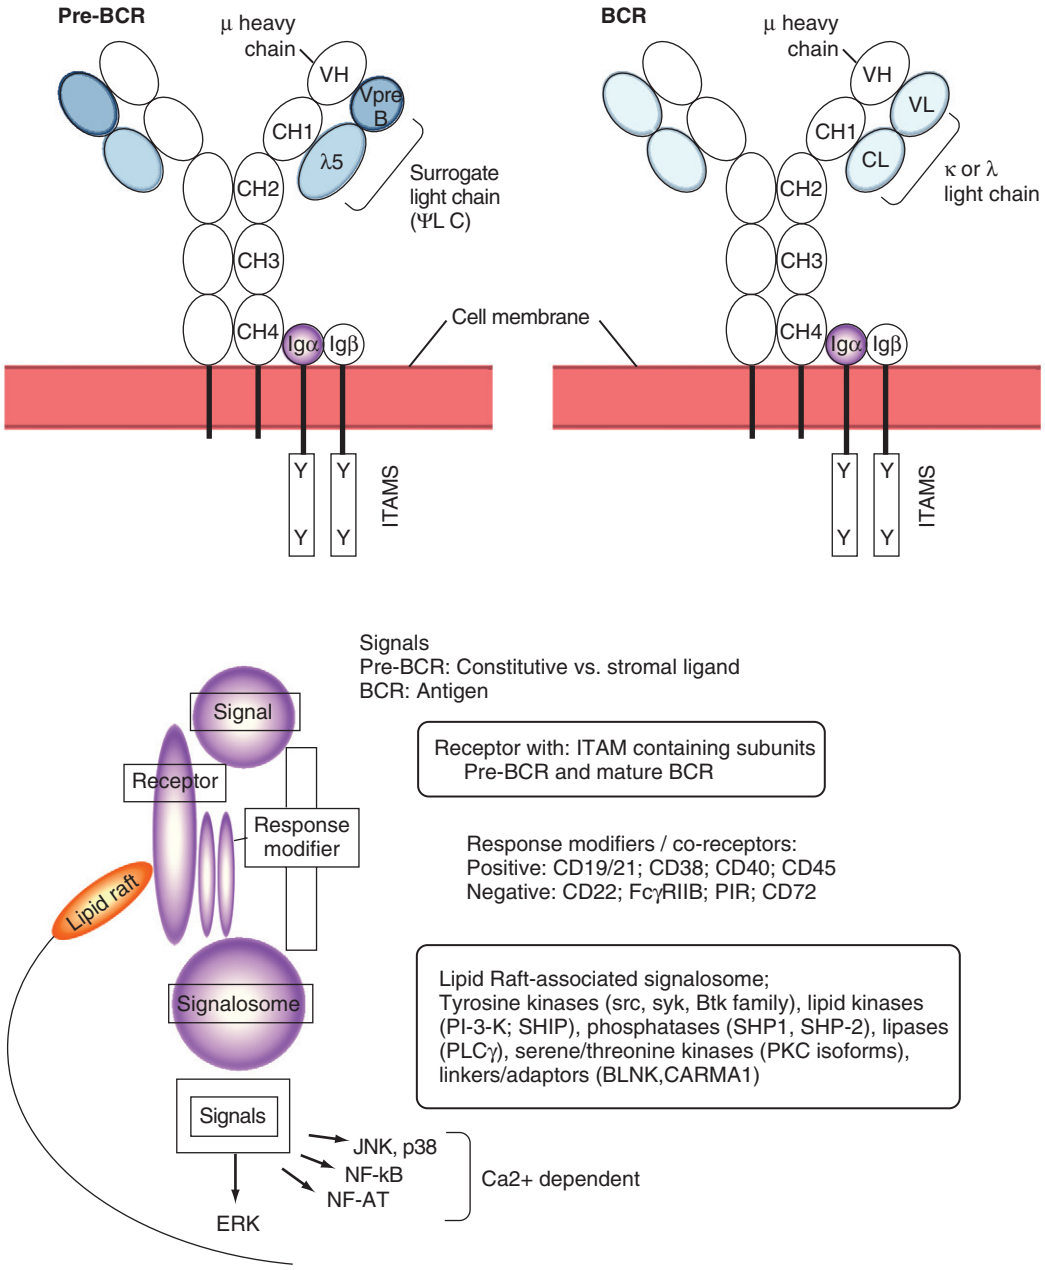

Figure 18-3 THE PRE-B-CELL RECEPTOR (PRE-BCR) AND B-CELL RECEPTOR (BCR) AND ASSOCIATED SIGNALING INTERMEDIATES. *Top,* μ heavy chain protein in pre-B cells is associated with the surrogate light chains v-pre-B and λ5 *(left)*. In newly produced B lymphocytes, μ heavy chain is associated with conventional light chain *(right)*. Associated with heavy chain in both pre-B and B cells are two additional transmembrane proteins, Ig–α and Ig–β, that contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function. *Bottom,* Expression of the pre-BCR (or possibly its binding to a stromal ligand) or binding of antigen to the mature BCR, respectively, initiates the assembly of a lipid raft, BCR-associated "signalosome" composed of multiple signaling molecules, ultimately leading to transcriptional events that promote cell proliferation, survival, and differentiation. *ERK,* Extracellular-signal-regulated kinase; *Ig,* immunoglobulin; *JNK,* Janus kinase; *NF-κB,* nuclear factor kappa-light-chain enhancer of activated B cells; *NFAT,* nuclear factor of activated T cells; *SHIP,* src homology 2 containing inositol phosphatase. *SHP,* src homology 2-containing protein tyrosine phosphatase;

in additional components of the pre-BCR signaling complex, including the μ–heavy chain, λ5, Igα, and the key B-cell adaptor protein BLNK (see Fig. 18-1).

THE PRE-B TO B-CELL TRANSITION

At some point, pre-BCR–expressing cells cease to proliferate and enter a resting phase. This change occurs coordinately with a cessation of surrogate light chain expression, reactivation of the recombinatorial machinery, and initiation of conventional light chain gene rearrangement. These events culminate in the expression of light chain protein.

Ig light chain protein can be encoded by the kappa (κ) or lambda (λ) genes (Fig. 18-4). Greater than 90% of murine B cells express κ protein. However, the proportions of human κ and λ proteins are more equivalent, with approximately 60% of human B cells expressing κ light chain protein. The human κ gene is located on

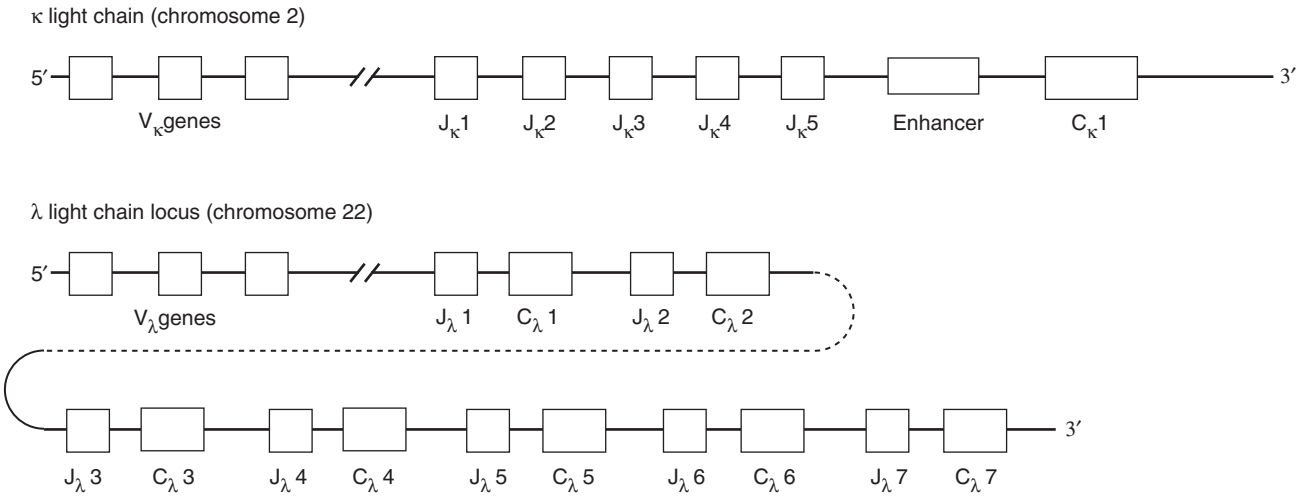

Figure 18-4 STRUCTURE OF THE HUMAN IMMUNOGLOBULIN LIGHT CHAIN GENES.

chromosome 2 and includes around 40 Vκ region genes, clustered in up to seven families, five functional Jκ region genes, and one C κ region gene. The human λ locus is located on human chromosome 22. Approximately 30 human Vλ genes exist and are grouped into 10 families. There are seven human Cλ genes, four of which are functional and three of which are pseudogenes. Each Cλ gene is located 3′ of a respective J λ gene. Light chain genes do not include D region loci.

Although B cells can express κ or λ light chain protein, rearrangements initiate at the κ locus, where the initial event is the joining of a V κ segment to a J κ segment. The VκJκ complex remains separated from the light chain C region by an intron, the entire complex is transcribed, and further splicing of the intron between the κ and C κ segment results in formation of a mature Vκ– Jκ–cκ transcript. If rearrangements at the first κ allele are unsuccessful, attempts are made to rearrange the second κ gene. If this fails, the λ locus is used. The regulation of light chain gene rearrangement is similar to that for heavy chain gene recombination. For example, the same enzymatic machinery involving the RAG proteins is necessary.

IMMUNOGLOBULIN CLASS SWITCHING

At the terminal stage of primary B-cell development, newly produced B cells can express both IgM and IgD. This coexpression occurs by means of alternative processing of a primary RNA transcript. As noted previously, the rearranged VHDJH heavy chain, part of the C region, and the intron separating these exons is transcribed after productive rearrangements in a cell. If the intron is spliced, resulting in association of the Cμ region with the VDJ complex, the B cell expresses IgM. Alternatively, if the Cμ exon is deleted along with the heavy chain intron, the VDJ complex and the Cδ exon become contiguous and the B cell expresses IgD. The differential processing of heavy chain transcripts within a single cell explains why some newly produced B cells coexpress both IgM and IgD (see Fig. 18-2).

These primary developmental events are distinguished from Ig class switching that allows the newly produced B cell to express the same VDJ complex associated with additional heavy chain C regions other than IgM and IgD. Deletions of germline DNA resulting in religation of the VDJ complex to these downstream heavy chain C region genes, such as γ3, γ1 γ2b, γ2a, ε and α are the mechanism by which this takes place. These DNA deletions are believed to occur at or near nucleotide sequences called *switch regions* that are located in the intron 5′ to each CH exon. As discussed subsequently, these class-switching events are highly regulated, secondary-differentiation events that occur in spleen and lymph nodes and are potentiated by helper T cells and their secreted products.[12]

THE B-CELL RECEPTOR

The structure of the BCR is similar to that described for the pre-BCR, except that κ or λ, rather than surrogate light chain proteins are associated with the Ig heavy chain. As shown in Fig. 18-3, the BCR consists of the Ig molecule and the associated Igα and Igβ proteins that are required for initiation of the intracellular signaling cascade after binding of antigen. This requirement exists because even though Ig heavy chains span the cell membrane, their cytoplasmic carboxyl tails are relatively short. For example, the intracellular C terminus of IgM and IgD consists of only three amino acids.

Antigen engagement of the BCR initiates assembly of a lipid raft, BCR-associated "signalosome," composed of multiple signaling molecules that include tyrosine kinases, serine/threonine kinases, lipid kinases, lipases, phosphatases, and linkers and adaptors.[13] This signalosome mediates a cascade of intracellular signals that includes the initiation of calcium influx. Additional calcium-dependent and -independent downstream signals that include the mitogen-activated protein (MAP) kinase cascade (c-jun N-terminal kinase [JNK], p38, extracellular-signal-regulated kinase [ERK]) and activation of key transcription factors that include JUN, c-fos, nuclear factor of activated T cells (NFAT), and nuclear factor kappa-light-chain enhancer of activated B cells (NF-κB) in turn mediate transcriptional events leading to cell proliferation, survival, and differentiation. The level and duration of receptor activation and hence transcriptional output are further modified by a series of cell surface coreceptors or "response modifiers" that bind to complement or to receptors on the surface of stromal cells, activated T cells, or other populations present in secondary lymphoid organs.

GENERATION AND SELECTION OF THE PRIMARY B-CELL REPERTOIRE

For the organism to mount an effective humoral immune response, an array of Igs with unique antigen-binding specificities, together referred to as the *Ig repertoire,* must be generated. Several mechanisms have evolved to ensure that this occurs.[14]

First, heavy and light chain proteins can be encoded by multiple germline V, J, and, in the case of the heavy chain, D region genes, and the combinatorial diversity among them is enormous. Second, nucleotides not encoded in the germline can be added to D-JH and VH-DJH junctions by a nuclear enzyme known as terminal deoxynucleotidyl transferase (TdT). Two splice variants of TdT, encoded by a single gene, have been identified, and it is the short (509-amino-acid) variant that catalyzes the addition of nontemplated nucleotides at coding joints. The long (529-amino-acid) form is a 3′-5′ exonuclease that catalyzes the deletion of nucleotides at coding joints. Thus,

N region diversity catalyzed by TdT may be attributable to the coordinated activities of short and long forms of that enzyme. Third, the DNA joints that form during recombination are often imprecise and can occur at any of several nucleotides in the germline. This junctional diversity has the potential to generate different amino acid sequences, resulting in added diversity of the Ig repertoire. However, out-of-frame joints that cannot be transcribed also may result. Finally, somatic mutation of V region genes can occur, usually in secondary lymphoid tissues. This latter process, which results in an increased affinity of the antibody for antigen, is discussed in more detail in the section on secondary B-cell development.

It is important to recognize that not all B-cell progenitors successfully mature into B lymphocytes. The remarkable cell loss that occurs during the process of differentiation of pro-B cells into B lymphocytes is attributable to a series of selection events. First, Ig heavy chain gene rearrangements are productive in approximately one-third of pro-B cells. In addition, functional light chain gene rearrangements do not occur in all pre-B cells. Those cells with nonproductive Ig gene rearrangements undergo apoptosis and are eliminated from the BM by resident macrophages and stromal cells.

Selection events also are operative on cells that have matured to the surface IgM stage of development. As a result, although approximately 2×10^7 IgM^+ immature B cells are produced daily in murine BM, only 10% to 20% of these cells survive to exit the BM and enter the spleen as transitional B cells. Some of these surface IgM^+ cells are eliminated because they are potentially self-reactive. Such self-reactive B cells may be generated because the process of Ig gene recombination is random.

Several mechanisms have been proposed to account for the fate of such self-reactive cells.[15] In some cases, the presence of self-antigen may not activate self-reactive B cells. This scenario may result from weak B-cell affinity for the antigen, or the autoantigen may be present at an extremely low concentration. In other instances, interaction of antigen with the autoreactive B cell may result in anergy. The level of membrane Ig on such anergic B cells may be reduced up to 20-fold, the cell's ability to proliferate may be impaired, and differentiation into Ig-secreting cells may be blocked. Finally, self-reactive B cells may be clonally deleted. Clonal deletion may result from cytolysis by other cells, such as BM macrophages, or autoreactive B cells may undergo a physiologic change resulting in cell death after receptor engagement.

The recognition of self-antigen by a B cell may not necessarily result in anergy or deletion but instead may lead to *receptor editing*. In this process, rearranged κ light chain alleles can be replaced by secondary rearrangements of upstream Vκ genes to downstream, unrearranged Jκ segments. These secondary rearrangements, which may delete the primary VκJκ complex or separate it from Cκ by inversion, are possible because of the continual presence of unrearranged Vκ regions upstream of the joined VκJκ coding segments. Receptor editing also can occur in peripheral B cells in response to antigen stimulation, as discussed subsequently.

REGULATION OF PRIMARY B-CELL DEVELOPMENT

Hematopoiesis occurs in the intersinusoidal spaces of the medullary cavity in association with a fixed population of stromal cells.[16] Stromal cells are largely sessile and form a three-dimensional hematopoietic microenvironment with which developing blood cells associate (Fig. 18-5). Before 1980, little was known about how stromal cells and their secreted products regulate B-cell development. However, advances in molecular biology, the isolation of BM stromal cells, and the development of long-term culture methods for growing B-lineage cells have converged in the past 3 decades. As a result, considerable insights into the regulation of B-cell development by extracellular signals have been obtained.

Cell–Cell Interactions

Direct contact between developing B-lineage and stromal cells can be observed on analysis of intact BM or of B lymphopoiesis in long-term BM cultures, and the molecular basis for these associations is being defined in both humans and mice. For example, both murine and human pre-B cells express the very late antigen 4 (VLA-4) integrin that interacts with a stromal cell ligand identified as vascular cell adhesion molecule-1 (VCAM-1). VLA-4 also promotes binding to fibronectin, an extracellular matrix protein. CD44 on developing B-lineage cells also has been implicated in mediating stromal cell–lymphocyte interactions in the mouse through binding to stromal cell–derived hyaluronate. These intercellular interactions presumably would allow B cells to receive proliferative or developmental signals (or both) from stromal cells. It is important to appreciate that the stromal cells may not be passive populations that constitutively provide these signals. Instead, the binding of the B-lineage cell may stimulate the stromal cell in turn to produce such differentiation or growth-potentiating activities.

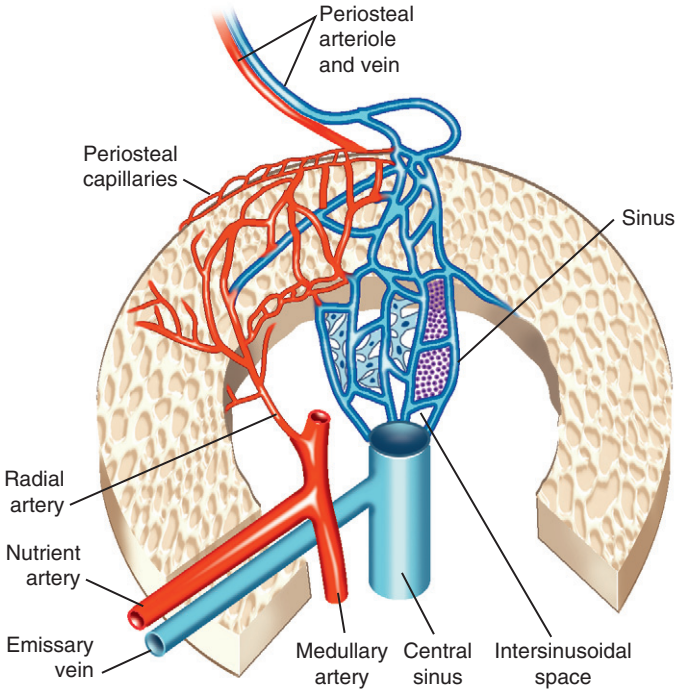

Figure 18-5 CROSS-SECTION OF BONE SHOWING ELEMENTS OF THE MEDULLARY CIRCULATION, THE MARROW SINUSOIDS, AND THE LOCATION OF STROMAL CELLS. *(From Dorshkind K: Regulation of hematopoiesis by bone marrow stromal cells and their products.* Annu Rev Immunol *8:111, 1990. Reprinted by permission from the Annual Review of Immunology.)*

Cytokines

An additional means by which BM stromal cells regulate the growth and differentiation of B-lineage cells is via the secretion of soluble mediators. The literature describing the effects of cytokines on B-cell development is extensive, and a discussion of each one is beyond the scope of this chapter. However, the focus can be narrowed considerably when only those factors with obligate effects on B-cell development are considered.

The critical B lymphopoietic cytokine in mice is IL-7, which binds to a cell-surface receptor formed by the IL-7 receptor α chain and the common cytokine γ chain. That IL-7 is required for murine B-cell development was demonstrated by studies showing that mice administered antibodies to IL-7 exhibit severe lymphopenia. Subsequent analysis of IL-7 and IL-7 receptor knock-out mice corroborated these studies. These animals also exhibit a severe T-cell depletion because IL-7 is required for thymopoiesis. Cells that have initiated Ig heavy chain D-JH rearrangements are particularly responsive to the growth-stimulating effects of IL-7. However, by the time they have

Table 18-1 Characteristics of B Cell Subpopulations in Mice and Humans

Cells	Function	Phenotype	Properties	Localization
B-1a (mouse)	Innate immunity	$IgM^{high}IgD^{low}CD11b^{+}CD5^{+}$ (in serous cavities)	Secretion of IgM natural antibodies	Serous cavities, spleen, gut
B-1b (mouse)	Innate immunity	$IgM^{high}IgD^{low}CD11b^{+}CD5^{-}$ (in serous cavities)	Antibody production is induced	Serous cavities, spleen, gut
MZ (mouse and human)	Innate immunity	$IgM^{+}IgD^{low}$ (human MZ B cells also include $CD27^{+}$ IgM^{+} unswitched memory cells)	Strong response to T-independent antigens	Splenic MZ
Follicular (mouse and human)	Adaptive immunity	$IgM^{low}IgD^{high}$	Strong response to T-dependent antigens	Spleen and lymph nodes; recirculate

IgD, Immunoglobulin D; *IgM*, immunoglobulin M; *MZ*, marginal zone.

matured to the late pre-B-cell stage of development, responsiveness to IL-7 attenuated. Subsequent murine studies revealed that in addition to its growth-promoting effects, IL-7 acts as a differentiation factor that potentiates the recombination of a VH region gene segment to an already rearranged DJH complex.

The precise role of IL-7 during human B-cell development remains to be determined. Human B-cell progenitors are IL-7 responsive, as shown in studies in which $CD34^{+}CD19^{+}$ pro-B cells proliferate in response to IL-7. The issue is whether IL-7 is an obligate human B-lymphopoietic factor as in mice. This question arises because B-cell development is normal in patients with X-linked severe combined immunodeficiency. These individuals have mutations in the gene encoding the cytokine common γ chain, which is part of the receptor for IL-2, IL-4, IL-9, and IL-15, in addition to IL-7. Further suggesting that IL-7 is not an obligate B lymphopoietic factor is that B-cell development also is normal in patients whose B-lineage cells express a mutated IL-7Rα chain. Additional studies to identify factors required for human B-cell development are needed.

Systemic Factors

In addition to regulation by microenvironmental factors, there is a growing appreciation that systemic factors, and those of endocrine origin in particular, also regulate B-cell development. For example, B-cell development in mice is dependent on the integrity of the pituitary–thyroid axis because mice deficient in the production of thyroid hormone or expression of the thyroid hormone receptor exhibit suppressed BM B lymphopoiesis. Whether or not these events also occur in human B lymphopoiesis has not been established. It also has been demonstrated that hormones can negatively affect B-cell development. In particular, increased levels of estrogens occurring during pregnancy inhibit lymphopoiesis.

B-1 B CELLS

The B cells that are produced in adult BM and that constitute the majority of B cells in the peripheral lymphoid tissues such as the spleen and lymph node are often referred to as B-2 B cells. This nomenclature serves to contrast them with another functionally distinct population of mature B cells that are referred to as B-1 B cells. B-1 B cells have been extensively studied in mice.[17,18] B-1 B cells constitute around 5% of total B lymphocytes in that species and are found in multiple tissues that include the spleen and serous cavities. Approximately half of the B cells present in the latter sites, including the pleural and peritoneal cavities, in most strains are B-1 B cells. B-1 B cells in serous cavities can be distinguished by their unusual phenotype. For example, peritoneal cavity B-1 B cells can be defined by their expression of high levels of sIgM; low levels of sIgD; and CD11b, a determinant expressed on myeloid cells. B-1 B cells can be further subdivided based on the differential expression of cell surface CD5 into $sIgM^{high}$ $sIgD^{low}$ $CD11b^{+}$ $CD5^{+}$ B-1a B cells, and $sIgM^{high}$ $sIgD^{low}$ $CD11b^{+}$ $CD5^{-}$ B-1b B cells. Both B-1 subpopulations are generally considered to be part of the innate immune system, although each mediates distinct functions. B-1a B cells are distinguished by their spontaneous secretion of IgM, which are often referred to as *natural antibodies,* and antibody production by B-1b B cells is induced after exposure to antigen (Table 18-1). Antibodies from both subpopulations of B-1 B cells have been shown to be required for protection against pathogens such as *Streptococcus pneumoniae*.

Classic studies demonstrating that the transplantation of neonatal liver cells into irradiated murine recipients most efficiently generated B-1 B cells but adult BM most efficiently repopulated B-2 B cells suggested that B-1 cells were a distinct B-cell lineage derived from progenitors that preferentially arose during fetal life.[18] The description of a phenotypically identifiable B-1 B cell–specified progenitor that is preferentially generated in fetuses has provided strong support that a significant number of B-1 cells are derived from distinct progenitors. In addition to this "lineage model," the "selection model" proposes that B-1 cells are conventional B-2 B cells that develop the distinguishing B-1 characteristics because of selective pressures after antigen exposure. That some B-1 cells are generated in this manner cannot be excluded.

Based on the expression of CD5 by murine B-1a cells, many studies have claimed to have identified human B-1 cells based on simultaneous expression of CD5 and sIgM. These reports must be viewed with caution because CD5 is not a B-1–restricted determinant. Thus, the existence of human B-1 cells has remained controversial. However, a $CD20^{+}$ $CD27^{+}$ $CD43^{+}$ $CD70^{-}$ population of cord blood B cells that has properties consistent with their being classified as human B-1 cells was recently described.[19]

FETAL B-CELL DEVELOPMENT

Murine blood cell formation initiates during embryogenesis, with the extraembryonic yolk sac and intraembryonic paraaortic splanchnopleura region being two of the earliest sites of hematopoiesis.[20] The potential of cells from both of those tissues to generate B lymphocytes has been demonstrated. Subsequently, cells that express B-lineage antigens that include cytoplasmic Ig can be detected in fetal liver and BM, and by late gestation, surface IgM^{+} B cells are present in multiple fetal tissues that include the spleen.

The analysis of human fetal B-cell development is more limited, but what is known generally parallels the murine data. For example, hematopoiesis initiates in the human yolk sac at 3 weeks of gestation, although whether or not B-cell potential is present at that time is unclear. Pre-B cells are present in human fetal liver by week 8 of gestation, and surface IgM^{+} cells are present at week 9. IgM expressing cells have also been observed in additional human fetal tissues that include the omentum, the peritoneal cavity, and the spleen.

Evidence from mouse studies suggests that the first B-cell potential to arise in fetuses is associated with the B-1 lineage.[21] For example,

the B-cell precursors in day 9.5 yolk sac and paraaortic splanchnopleura primarily generate B-1 cells. Also, the first B lineage cells to arise in fetal liver have a phenotype consistent with B-1 progenitors.[22] Only later during gestation and subsequent to the emergence of HSCs on day 10.5 are B-2 progenitors detected in appreciable numbers. The sequential emergence of B-1 and B-2 cells is consistent with the layered immune system hypothesis, which proposes that distinct waves of lymphopoiesis that generate B cells with increasingly sophisticated functions emerge.[23] Evidence indicates that selected T cells, γδ T cells in particular, also develop in a layered manner. It has been suggested that B-cell development occurs in distinct waves in the human fetus as well.[24]

SECONDARY LYMPHOID COMPARTMENTS

After newly produced B cells exit the BM, they migrate to the spleen, where they undergo further maturation into follicular (FO) B cells or marginal zone (MZ) B cells. In general, FO B cells are poised to respond to T-dependent antigens, which, as their name implies, require help from T cells. The T cells in the spleen that provide this help are located in the periarterial lymphoid sheath (PALS) (see Fig. 18-6).

The spleen (but not lymph nodes) contains additional B cells located at the outer limit of the splenic white pulp (see Fig. 18-6). This area, known as the MZ, is where the MZ B cells localize, and the region also contains macrophages and dendritic cells. MZ B cells present in this region play a critical role in the response to T-independent antigens (see later discussion). Human MZ B cells are clearly heterogeneous and include a large proportion of $CD27^+$ IgM^+ unswitched memory B cells with somatically mutated Ig heavy chains. The origin of this cell population is unclear but is presumed to be antigen driven yet may not require T-cell help. Although MZ B cells in rodents appear to be a static, nonrecirculating population, cells with a $CD27^+$ IgM^+ phenotype are clearly present in human peripheral blood as well as other lymphatic tissues. This circulating population becomes detectable in parallel with seeding of the splenic MZ (typically after 2 years of age), increases in number after exposure to polysaccharide antigens, and appears to play an essential role in the rapid response to infection with encapsulated bacteria.[25]

Marginal zone and FO B cells are the progeny of $sIgM^+$ B cells produced in the BM. However, the latter cells are functionally immature and migrate to the spleen, where they undergo maturation through various transitional B-cell stages that results in the generation of MZ and FO B cells. The most immature transitional cells are referred to as *transitional 1 (T1) B cells,* which localize at the outer edge of the PALS (see Fig. 18-6). The PALS in mice is occupied by a considerable number of T cells but in humans few T cells are present in this region. T1 B cells give rise to a more mature population of splenic B cells, referred to as *transitional 2 (T2) cells*.[26]

The T1 and T2 populations respond differentially to developmental stimuli, and a considerable degree of selection occurs during the T1 to T2 transition. For example, T1 cells with BCR specificities for bloodborne self-antigens are deleted by negative selection. Positive selection via BCR signaling must occur, and if it does not, the T2 cells will die by neglect. The survival of T2 cells, but not T1 cells, is also dependent on the B-cell growth factor BAFF (BLyS, TALL-1, THANK, zTNF4), which is produced by the splenic microenvironment. A fraction of T2 cells are no longer in G_o phase of the cell cycle, suggesting they are in a more activated state than is the case for T1 cells.

Various signals determine whether T2 cells mature into MZ or FO B cells. Weak signaling through the BCR along with engagement of the Notch2 receptor promotes entry into the MZ B-cell compartment. There is a marked depletion of MZ B cells when the Notch2 pathway is blocked. Self-reactive B cells are enriched within the MZ population, suggesting that weak self-antigens may play an important role in their generation. This feature may permit them to respond rapidly to cross-reactive epitopes on pathogens as discussed later. BCR signals, along with activation of the alternative NF-κB pathway,

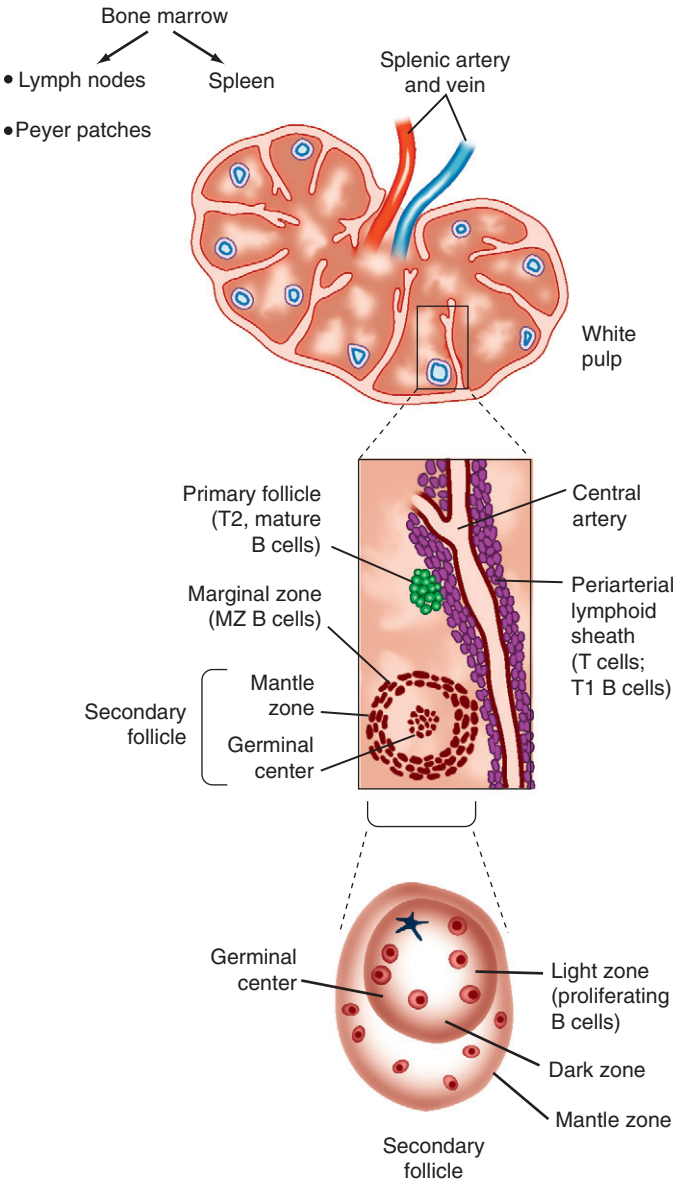

Figure 18-6 ORGANIZATION OF B CELLS IN SECONDARY LYMPHOID ORGANS WITH EMPHASIS ON THE SPLEEN.

are required for T2 cells to mature into an FO B cell. It is estimated based on murine studies that only 1% to 3% of splenic transitional B cells develop into mature, naïve B cells. When mature, naïve B cells are generated, they recirculate and take up residence in various lymphoid tissues that include lymph nodes, intestinal Peyer patches, and the spleen itself. Within these tissues, mature naïve cells localize in clusters of B lymphocytes, and each such cluster is termed a *primary follicle* (see Fig. 18-6). Within these regions, the FO B cells are poised to respond to antigen and undergo the germinal center reaction described below.

The molecular signals responsible for the intraorgan localization of specific B-cell populations and their migration patterns after antigenic challenge are being identified.[27] Proper segregation of splenic B cells in follicles and the MZ is dependent on expression of tumor necrosis factor (TNF) and lymphotoxins α and β (LTα and LTβ). Signaling through lymphocyte function-associated antigen (LFA-1) and α4β1 integrins also has been implicated in localization and retention of MZ B cells. These molecules and their receptors may also transmit signals required for the development of stromal cells that

produce chemokines required for movement of cells among different anatomic locations within secondary lymphoid organs. A role for chemokines in B-1 B-cell localization to the peritoneal cavity has also been demonstrated.

T-INDEPENDENT B-CELL RESPONSES

T-independent responses are elicited by polymeric antigens, such as polysaccharides, that are composed of repetitive antigenic epitopes. MZ B cells play a critical role in these responses. On antigen binding, MZ B cells undergo rapid proliferation and maturation into plasma cells that secrete low-affinity IgM.

The rapid response of MZ B cells to antigen has led to the idea that this effector population, similar to B-1 B cells, constitutes a key element of the innate immune response to bacterial and other selected pathogens. Because they have a low activation threshold, MZ B cells rapidly differentiate into antibody-forming cells in response to antigen. These cells secrete primarily low-affinity IgM and IgG3 antibodies that provide a first line of defense. This response may be reinforced by B-1 B cells, whose Ig repertoire is designed for responsiveness to the polymeric antigens that characterize the T-independent response. In view of this, it is not surprising that many of the properties of MZ B cells overlap with those of B-1 B cells (see Table 18-1). The poor response of infants to some types of T-independent antigens correlates with the fact that the MZ is not fully formed until the age of 1 to 2 years. In addition, splenectomized individuals are more susceptible to infection with some bacteria, owing to the deficient antibody response to capsular polysaccharides.

T-DEPENDENT RESPONSES

Although some B cells in the MZ can respond to T-dependent antigens, most B cells that do so are the mature, naive FO B cells located in primary follicles. As described previously, these cells are derived from T2 B cells and have subsequently migrated into the primary follicle. After their binding of a T-dependent antigen (as soluble antigen, indirectly via presentation by a local antigen presenting cell, or as an immune complex) mature, naïve B cells in primary follicles undergo a blastogenic response. Some of these cells will immediately mature into plasma cells that secrete low-affinity IgM to provide a rapid initial response to infection. In response to T-cell help, however, other B cells undergo further proliferation and differentiation. The histologic appearance of the follicle changes as these events evolve. The nonresponsive B cells form an outer *mantle zone* surrounding the proliferating, antigen-responsive B cells in a central germinal center.[28]

Germinal center B cells are shielded from soluble antigens and are exposed only to a unique set of antigens presented by follicular dendritic cells. Two regions can be distinguished within the germinal center of the secondary follicle. At one pole, the cycling B-cell blasts are referred to as *centroblasts* and form the *dark zone*. The other pole, referred to as the *light zone,* consists of nonproliferating cells referred to as *centrocytes*. Some of these centrocytes go on to become plasma cells, but others become memory B cells (see Fig. 18-6). The end result of the germinal center reaction is the formation of plasma cells that secrete high-affinity Ig. Other germinal center B cells convert to memory B cells, which constitute about 40% of all B cells and are responsible for the relatively rapid response observed on secondary exposure to the same antigen.

AFFINITY MATURATION AND LYMPHOMAGENESIS

After the initial low-affinity IgM response that helps to keep a developing infection in check, the response of B cells in the germinal centers to T-dependent antigens involves Ig class switching and selection of B-cell clones of higher affinity antigen-binding potential**.** This process is known as *affinity maturation*.

Affinity maturation results in the selection of B cells estimated to have a 10-fold or even greater**,** increase in antigen-binding potential. Analysis of Ig gene sequences of pre– and post–germinal center B cells indicates that this increased affinity is secondary to changes in the genes that encode the antigen-binding domain of the Ig molecule. These genomic changes result from three types of modifications. First, as described previously, B cells may undergo receptor editing. Receptor editing usually involves modifications of the existing light chain in which an upstream V region segment joins to a downstream J region gene. As a result, the genetic region encoding the originally expressed light chain is deleted. For this process to occur, RAG-1 and RAG-2 expression are required. It has been proposed that B cells in germinal centers might reactivate *RAG* gene expression to mediate events such as receptor editing. However, that this occurs has been questioned. Instead, receptor editing in splenic B cells may be limited to a small subset of recent immature BM immigrants that enter germinal centers before their *RAG* gene expression has been extinguished.

Somatic hypermutation provides a second means to increase antibody affinity. During this process, single-nucleotide exchanges, deletions, and mutations are introduced into the genes encoding the antibody-binding regions of the Ig receptor. Finally, Ig class switching (see earlier) can occur. Class switching results in the replacement of the existing heavy chain constant region by a downstream constant region gene. Recently, a B cell–specific gene that encodes activation-induced cytidine deaminase (AID), which is expressed in germinal center B cells, has been identified. AID is a putative RNA-editing enzyme that acts as a cytidine deaminase and has been shown to be indispensable for somatic hypermutation and class switch recombination.[29]

Affinity maturation is dependent on signals delivered to the antigen-responsive B cells by antigen-specific T lymphocytes that migrate into the germinal center from the PALS. T cells mediate their effects on B cells through the secretion of cytokines as well as through direct intercellular contacts, and these stimuli result in B-cell growth, differentiation, and Ig class switching. For example, CD40 is a T cell–surface glycoprotein encoded by a member of the tumor necrosis gene family, and its ligand is expressed on B cells. CD40 ligand knock-out mice do not form germinal centers, and humans who do not express CD40 ligand have X-linked hyper IgM immunodeficiency. Another key T-cell costimulatory signal includes the cytokine IL-10, which is secreted by T cells in response to their activation via the "inducible costimulator" ICOS. Humans lacking expression of ICOS on T cells have adult-onset common variable immune deficiency, leading to a severe deficit in generation of class-switched and memory B cells.

There are two unintended consequences of affinity maturation. One is that autoreactive clones may be inadvertently generated. The other is the development of B-cell lymphoma. Lymphomagenesis results in part from the fact that vigorous B-cell proliferation combined with the changes at the DNA level that lead to molecular alterations promoting or support malignant transformation. Numerous studies have assigned B-cell lymphomas to each of the normal B-cell counterparts (as described). Events that limit differentiation of immature or activated mature B cells can also promote malignant transformation.

AGING AND B-CELL DEVELOPMENT

Studies of both rodents and humans have demonstrated that the quality of the immune response is diminished with age. Such declines are not incompatible with life, but they may become a factor when the individual is required to mount an immune response to a novel pathogen, respond to vaccination or when considering the use of BM-derived from older donors. Consequently, defining how aging affects the immune system is critical in order to develop strategies to augment immunity in the elderly.

Studies of mice have established that the production of B cells from HSCs is severely attenuated with age. For example, the

frequency and total number of CLP, pro-B cells, and pre-B cells is significantly reduced in the BM of old mice. This also seems to be the case for human B-cell development as well. B-cell progenitors from young and old mice have been compared in order to identify patterns of gene expression that underlie the decline in B-cell production with age. This has led to the identification of multiple genes that include E2A as well as $p16^{Ink4a}$ and Arf. The latter two genes are part of the Cdkn2a locus, and the proteins they encode function as potent tumor suppressors. Levels of $p16^{Ink4a}$ and Arf expression increase in pro-B cells with age, and this in turn results in diminished proliferation and increased apoptosis of B-cell progenitors.

Why these changes in primary B-cell development occur is under intense study. One possibility is that HSCs and lymphoid progenitors are genetically programmed to age. An alternative hypothesis is that aging in HSCs and lymphoid progenitors is secondary to changes in the local and systemic environments. Further studies to distinguish between these possibilities are needed.

Regardless of why B-cell production declines, the end result is a lower number of newly produced, naïve B cells that enter secondary lymphoid tissues such as the spleen. Senescence also affects mature B cells resident in peripheral lymphoid tissues. For example, in addition to an accumulation of memory B cells in the spleen of old mice, the Igs they produce are less protective because of low titer and affinity. Some of these defects may be intrinsic to the B cells but others may be secondary to age-related defects in T cells.[30]

CHAPTER 19

T-CELL IMMUNITY

Shannon A. Carty, Matthew J. Riese, and Gary A. Koretzky

Thymus-derived (T) lymphocytes play an essential role in the immune response to pathogens and against host cells that have undergone malignant transformation. T cells are critical regulators of other arms of the immune system via soluble mediators they produce and through direct interactions between ligands on the T-cell surface and receptors on other immune cells. This chapter first reviews T-cell activation after engagement by specific antigen and how signals delivered by the antigen receptors shape the repertoire of mature T cells in secondary lymphoid organs. The chapter then discusses how different populations of mature T cells exert their effector functions. Because homeostasis of the immune system requires not only that T cells become activated under appropriate conditions but also that their activity be curtailed when the pathogenic challenge has been met, the chapter describes several means by which T-cell activation is terminated. Finally, the chapter reviews advances in drug development that make use of our understanding of the molecular basis for T-cell activation.

T-CELL ACTIVATION

T-cell activation begins when a T cell encounters a specific antigen that engages and then initiates signal transduction through the T-cell antigen receptor (TCR). Unlike B cells that respond to soluble antigens, T cells are stimulated by small peptides presented on the surface of other cells. These peptides are incorporated into the binding groove of proteins of the major histocompatibility complex (MHC, known in humans as human leukocyte antigen [HLA] complexes) through a process called *antigen presentation*. Thus, the ligand for the TCR is a peptide surface that is generated by both amino acids from the antigenic peptide and residues found in the MHC molecules themselves. Engagement of peptide–MHC complexes by the TCR induces a series of intracellular biochemical events that culminate in T-cell activation. Although T cells make use of many of the same biochemical pathways used by other cells for activation, a number of molecules are unique to immune cells that are critical for T-cell activation. This section discusses TCR signal transduction, focusing on immune cell specific molecular events.

Antigen Presentation: Creating the Ligand for the T-Cell Receptor

Invading pathogenic bacteria and viruses use different strategies to survive within infected hosts. Many bacteria, such as the pathogens staphylococci, streptococci, and various enteric Gram-negative bacilli, survive in the extracellular milieu, but viruses and other bacteria, such as *Listeria* spp., survive inside host cells. Successful elimination of pathogens in each of these locations requires distinct responses from the host. T cells play a central role in the control of extracellular and intracellular pathogens; however, the subset of T cells differs for each type of pathogen, with T cells expressing the cell surface marker CD4 most important for the response against extracellular pathogens and those expressing the CD8 marker essential for control of intracellular organisms. Whereas stimulated $CD4^+$ T cells act on other cells of the immune system by producing cytokines, soluble mediators that elicit a variety of cellular responses important for clearance of extracellular pathogens, $CD8^+$ T cells function largely by directly lysing host cells that have become infected with an intracellular organism. It is therefore critical for antigens derived from extracellular sources to stimulate $CD4^+$ T cells and for antigens derived from within the cell to stimulate $CD8^+$ T cells. Whether a particular antigenic peptide stimulates a $CD4^+$ versus a $CD8^+$ T cell is determined by which MHC proteins present the peptide to the TCR.

Class II MHC proteins are found on cells of the innate immune system known as "professional" antigen-presenting cells (APCs) as well as B cells and the thymic epithelium. Professional APCs include dendritic cells (DCs) and various tissue macrophages, which engulf extracellular organisms (often after these are coated with host antibodies), host cells that have undergone apoptosis (programmed cell death), and cellular debris through an endocytic pathway that brings the ingested material into contact with degradative enzymes. The peptides that are formed in these reactions are bound to the MHC class II proteins for presentation to $CD4^+$ T cells. The MHC class II complex is a dimer consisting of a single α chain and a single β chain. Both α and β contribute to peptide binding and interaction with the TCR. As they are being synthesized within the cell, MHC class II complexes bind invariant chain (Ii), a protein that directs the newly formed MHC proteins into an acidic vesicle. During this trafficking event, a portion of the Ii occupies the peptide binding site. When the MHC class II protein reaches the acidic vesicle, Ii is proteolyzed by cathepsin S, leaving behind a small fragment that remains lodged within the peptide-binding cleft of the MHC class II complex. This fragment is termed the *class II–associated invariant chain peptide (CLIP)*. The MHC class II containing vesicles then fuse with other vesicles containing the peptide fragments from the endocytosed particles. There, CLIP is replaced with a peptide, thus stabilizing the MHC class II complex and allowing it to be transported to the cell surface, where it interacts with $CD4^+$ T cells (Fig. 19-1).

All cells of the body are at risk of being infected with intracellular pathogens or becoming transformed. Because protection against such challenges requires a $CD8^+$ T-cell response, all nucleated cells in the body express class I MHC, the protein complex that presents antigen to $CD8^+$ T cells. Similar to class II MHC, class I MHC is a protein dimer. However, in contrast to class II, only the α chain of class I is variable. This α chain is associated with $\beta 2$ microglobulin, which stabilizes the complex but plays no direct role in antigen presentation. During its assembly in the endoplasmic reticulum (ER), the MHC class I complex comes into contact with peptides derived from proteins being translated in the cell. During protein synthesis, small amounts of protein are modified by ubiquitinylation. This serves as a targeting sequence, directing the modified protein to the proteosome, where it is degraded into small peptide fragments. These fragments are transported back into the ER by the transporters associated with antigen processing (TAP-1 and TAP-2), where they become available for binding to the newly synthesized MHC class I complexes. Peptide association completes the folding and assembly of MHC class I, which is then transported to the cell surface, where it can be recognized by $CD8^+$ T cells.

T cells can only respond to antigenic peptides if these peptides fit into the binding pocket of either MHC class I or II. Although a large number of peptides are able to bind to a specific MHC complex, the

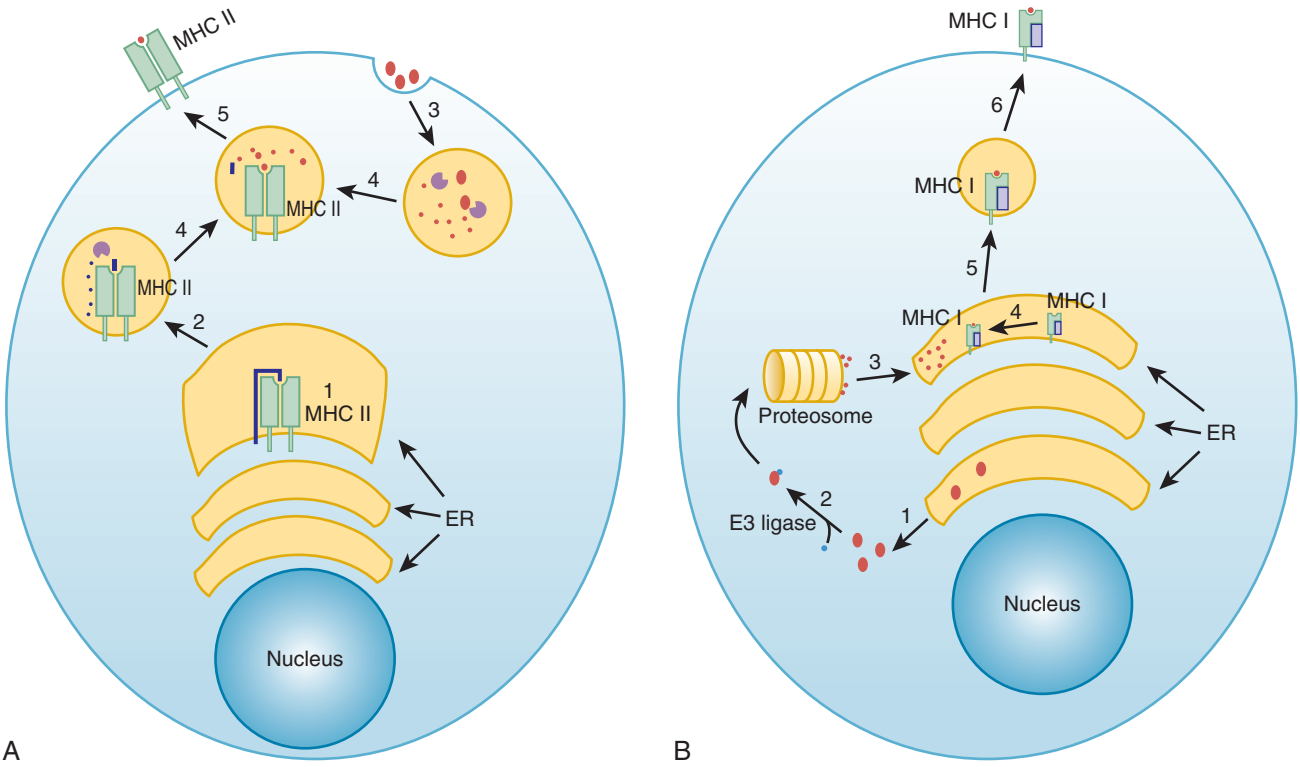

Figure 19-1 ANTIGEN PRESENTATION. Presentation of peptides by major histocompatibility complex (MHC) class I and class II molecules occurs by different mechanisms. **A,** Processing and presentation of class II peptides is limited to specialized antigen-presenting cells (APCs). *(1)* MHC class II molecules are synthesized in the APC endoplasmic reticulum (ER) in conjunction with a stabilizing protein known as invariant chain (Ii) *(purple)*. *(2)* After transport into intracellular vesicles, proteases degrade Ii chain, leaving only the peptide class II–associated invariant chain peptide (CLIP) in the antigen presentation cleft of the class II molecule. *(3)* Peptides for MHC class II molecules are generated from extracellular proteins that are endocytosed from the surrounding milieu and degraded by proteases in intracellular vesicles after vesicle acidification. *(4)* Class II peptides are exposed to MHC molecules after fusion of peptide-containing vesicles and vesicles containing CLIP-loaded MHC class II complexes. After exposure to peptide, CLIP is replaced with a peptide derived from the ingested materials, and the vesicle moves to the plasma membrane, depositing the peptide-loaded class II molecule at the cell surface *(5)*. **B,** All nucleated cells are capable of processing and presenting MHC class I peptides. Peptides for MHC class I molecules are generated from intracellular proteins that are synthesized in the ER *(1)* and transported into the cytosol. *(2)* A fraction of these cytosolic proteins become ubiquitinated by E3 ubiquitin ligases that target their proteolysis by the proteosome. Resultant peptides are subsequently transported back into the ER *(3)* and loaded onto MHC class I molecules *(4)*. Peptide-loaded MHC class I molecules bud into vesicles *(5)* that fuse with the plasma membrane *(6)*, resulting in cell surface expression.

diversity of antigen presentation is enhanced through expression of three different MHC class I alleles (in humans, HLA A, B, and C) and class II alleles (in humans, HLA DR, DP, and DQ). To increase the spectrum of peptides any particular cell may present even further, MHC alleles are always co-dominantly expressed. Thus, any individual expresses a large number of different class II dimers on its APCs and class I dimers on all nucleated cells, providing excellent protection against potential pathogenic organisms. It is possible, however, that even with this degree of potential for antigen presentation, pathogens may evolve that do not possess unique proteins with sequences to fit into the MHC grooves. To circumvent this problem, the MHC locus evolved to be highly polymorphic, thus providing enormous diversity within the population for antigen presentation, ensuring that some individuals will express MHC dimers that can present antigen from virtually any pathogen. Interestingly, predominant MHC alleles exist in different parts of the world, suggesting that there is local pressure, perhaps based on prevailing microorganisms, that shapes selection of MHC expression.

Neither MHC class I nor class II complexes distinguish foreign from host peptides as they fill their peptide binding grooves. Because MHC class II samples all ingested antigens and class I is stabilized by a sampling of all proteins produced by the cell, the majority of the MHC complexes are filled with self peptides. The T cell must distinguish self from nonself to ensure that a response is only directed against that which is foreign. Control over what antigens elicit a T-cell response is accomplished through selection of a population of T cells expressing appropriate TCRs, as discussed later (see T-Cell Development).

The T-Cell Receptor Complex

The TCR is a multimolecular complex with separate components able to bind ligand or to transduce an activating signal to the cell. The peptide–MHC binding regions of the TCR consist of an α/β heterodimer in the majority of T cells and the related γ/δ heterodimer in a smaller subset of T cells. Both α and β and γ and δ consist of variable and constant regions. Similar to antibodies (see Chapters 18 and 22), the variable regions of the TCR antigen-binding proteins arise from rearranging gene segments that are imprecisely joined during T-cell development. This process allows for an extraordinarily diverse repertoire of potential antigen reactivity, although there are in total only several hundred genes that make up the α, β, γ, and δ loci. The germline configuration of the α and β loci are different, such that the α-chain locus comprises about 70 variable (V) segments, 60 joining (J) segments, and one (C) constant segment, but the β-chain locus comprises 50 V regions, 2 diversity (D) segments, 13 J segments, and 2 C regions. Greater diversity is generated by the addition of nucleotides between the V and J gene segments on α chains and the V, D, and J segments in β chains during the formation

of the mature TCR. In total, it has been calculated that approximately 10^{18} different TCRs can be created from these segments, although the functional population is much smaller because of the requirements for selection during maturation in the thymus (see T-Cell Development). Thus, after it has completed its developmental program, an individual T cell expresses a unique TCR encoded by a combination of gene segments that have been altered and rearranged (Fig. 19-2). The T cells circulating through the lymphatics, lymph nodes (LNs), and spleen possess sufficient diversity so that nearly all pathogens encountered express an antigenic sequence recognized by a circulating T cell, which then expands in number to combat that pathogen.

Soon after identification of the genes encoding TCR α and β, gene transfer studies in cell lines provided definitive proof that the α/β heterodimer itself contains all of the information necessary for peptide–MHC binding and is the protein complex that confers specific antigen reactivity on a particular T-cell clone. It also became apparent that although sufficient to bind peptide–MHC, the α/β heterodimer is not capable of transmitting an intracellular signal after ligand is bound. A series of studies, first in cell lines and then in mouse models, demonstrated that the signal transduction function of the TCR complex resides in a protein complex that associates noncovalently with the α/β dimer. This complex, CD3, is required

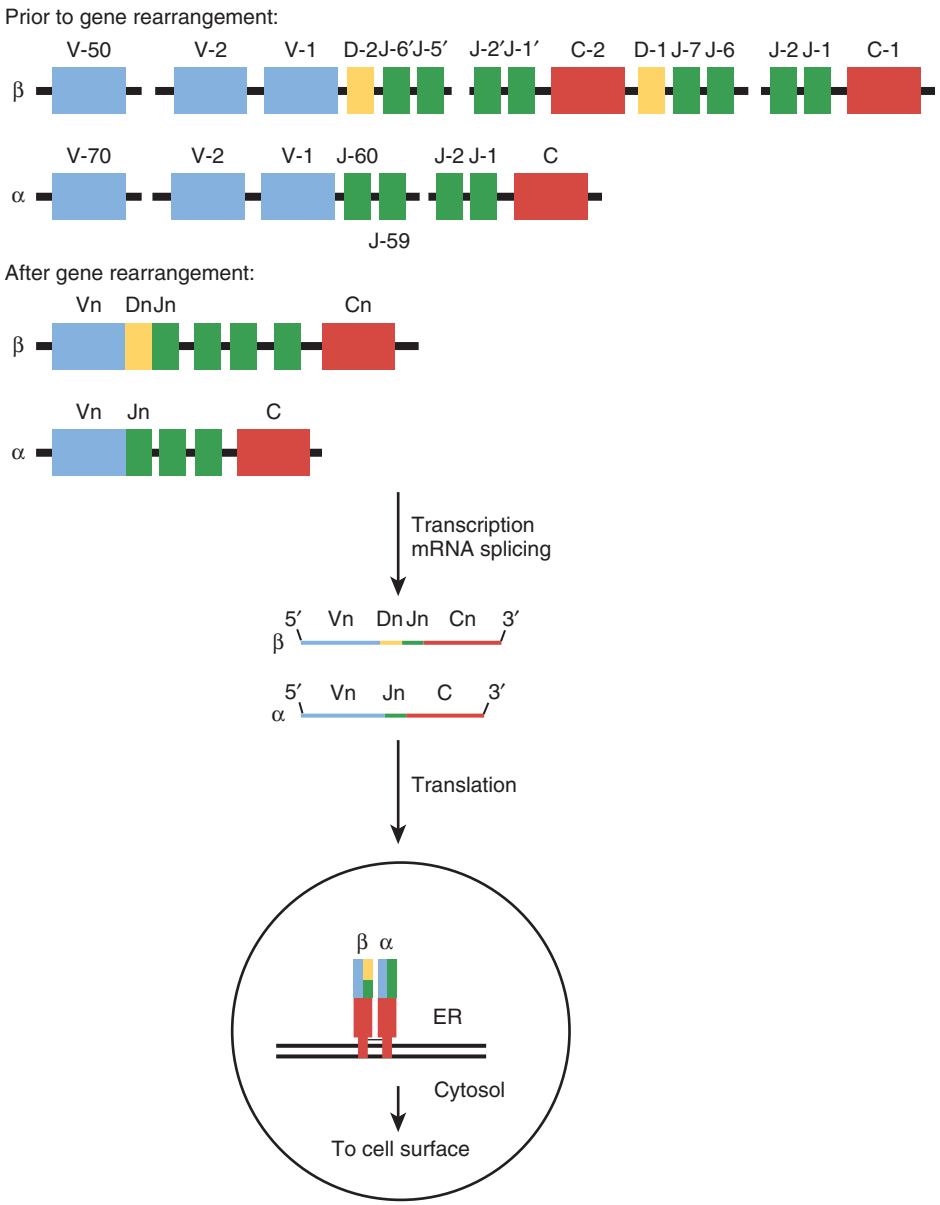

Figure 19-2 GENERATION OF DIVERSITY OF THE T-CELL ANTIGEN RECEPTOR. To generate the diverse repertoire of antigen receptors needed for protective T-cell immunity, the genetic loci encoding the two proteins of the T-cell receptor (TCR) undergo multiple rearrangements to form the mature α and β chains. For the β chain, DNA recombination occurs between a variable (V) segment, a diversity (D) segment, and a joining (J) segment to create, along with remaining joining segments and a constant region, an mRNA transcript. This transcript is spliced to remove intervening joining regions, creating the final mature β chain mRNA. For the α chain, recombination takes place between a V segment and a J segment, with the insertion of additional nucleotides between the recombined segments. As with the β chain, mRNA processing removes intervening J segments to permit translation of the mature α chain. After translation, β chains and α chains pair to form the TCR heterodimer that is transported to the cell surface. Note that peptide-binding regions of the TCR are generated from the recombined V(D)J segments of the TCR gene.

both for stable expression of the ligand-binding components of the TCR and for signal transduction. CD3 is composed of three subunits, δ, ε, and γ, expressed as heterodimers (γ/ε and δ/ε) along with the ζ subunit, which is present as a homodimer. Each subunit contains immunoreceptor tyrosine-based activation motifs (ITAMs), a stretch of amino acids with discretely placed tyrosine residues: one ITAM in δ, ε, and γ and three ITAMS in ζ. The ITAM tyrosines are key for the CD3 and ζ chains to transduce signals and are inducibly phosphorylated upon engagement of the α/β TCR chains by peptide–MHC. Upon their phosphorylation, the ITAMs become docking sites for other proteins that initiate the signaling cascade for T-cell activation. Notably, the CD4 or CD8 protein also plays a role in mediating signal transduction. These coreceptors bind both the appropriate MHC complex (MHC I for CD8, MHC II for CD4), and via their cytoplasmic tails, the signaling molecule Lck, one of the kinases capable of phosphorylating the ITAMs (Fig. 19-3).

T-Cell Receptor Signal Transduction

After the genes were cloned for each TCR complex component, it became clear that unlike many other cell surface receptors that transduce activating signals, neither the ligand-binding domains nor the CD3 proteins of the complex have intrinsic enzymatic function. Engagement of the TCR by the peptide–MHC was found to result in the rapid activation of protein tyrosine kinases (PTKs) within the T cells. Exactly how TCR engagement initiates PTK activation remains unclear; however, clustering of TCRs on the cell surface with resultant conformational changes in the CD3 proteins appears critical in the process. Src family (Lck and Fyn) PTKs are activated first after TCR stimulation, and the tyrosines within the CD3 and ζ ITAMs are substrates of these kinases. Phosphorylation of the ITAM tyrosines makes these residues able to bind to Src homology 2 (SH2) domains of other proteins. The most important SH2 domain-containing protein that is recruited to the ITAMs is ζ-associated protein of 70 kDa (ZAP-70), a PTK itself and a member of the syk family of proteins. Thus, binding of the TCR by ligand converts an enzymatically inactive receptor complex into an active PTK through recruitment and activation of cytosolic proteins.

Activation of ZAP-70 leads to tyrosine phosphorylation of a number of substrates, including enzymes that catalyze reactions generating second messengers important for T-cell activation. Phospholipase Cγ1 (PLCγ1) is activated by its tyrosine phosphorylation to cleave phosphatidylinositol-(4,5)-bisphosphate (PIP_2) into the second messengers diacylglycerol (DAG) and inositol-(1,4,5)-triphosphate (IP_3). DAG is a lipid second messenger that binds to and activates downstream signaling components, including protein kinase Cθ(PKCθ) and the Ras guanine exchange factor RasGRP. PKCθ, a member of the PKC family of serine/threonine kinases, regulates numerous effectors of gene transcription and T-cell effector function development, including the transcription factors nuclear factor κB (NF-κB) and activator protein-1 (AP-1). RasGRP is responsible for activating the small-molecular-weight guanosine triphosphate (GTP)-binding protein Ras by enhancing Ras release of guanosine diphosphate (GDP) allowing it to assume its activated GTP-bound form. Active Ras collaborates with PKC family members to stimulate transcription of new genes by activating mitogen-activated protein kinase (MAPK) family members. IP_3 mobilizes calcium stores from the ER. This increase in calcium is important for enzyme function, most notably the phosphatase calcineurin that dephosphorylates nuclear factor of activated T cells (NFAT), allowing it to translocate to the nucleus and transactivate genes important for T-cell proliferation, such as the gene encoding interleukin-2 (IL-2).

Although early TCR signal transduction studies demonstrated the importance of TCR-initiated PTK activity for T-cell activation, it took longer to unravel how this PTK activation drives the many critical second messenger cascades. This mechanism was elucidated with the identification and characterization of adapter proteins, which possess modular domains important for intermolecular interactions. Two central adapters in the TCR signaling pathway are linker of activated T cells (LAT) and SH2 domain-containing leukocyte protein of 76 kDa (SLP-76). LAT is a transmembrane protein with

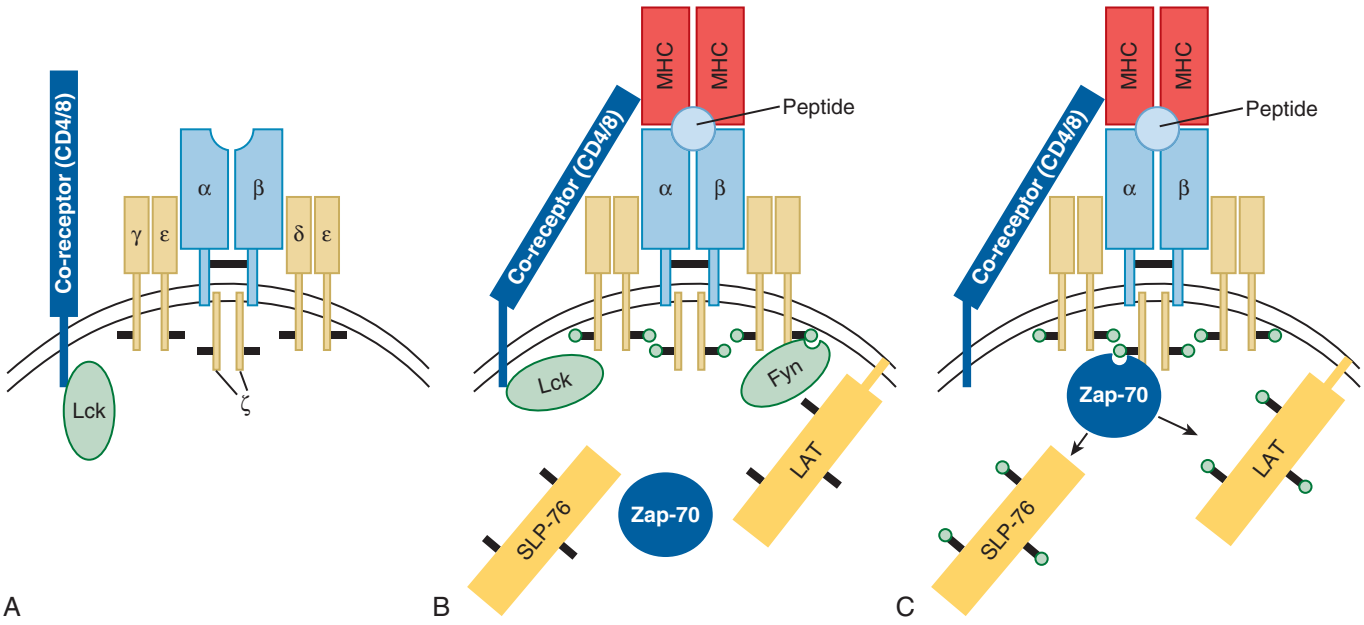

Figure 19-3 PROXIMAL T-CELL RECEPTOR (TCR) SIGNAL TRANSDUCTION. Binding of major histocompatibility complex (MHC) and peptide to the TCR and corresponding coreceptor (CD4 for MHC class II complexes and CD8 for MHC class I complexes) results in a series of molecular events that culminate in T-cell activation. **A,** At rest, the TCR exists in a complex with CD3, which consists of heterodimers between δ, ε, or γ (δ/ε, γ/ε) chains (*olive, left* or *right* of the TCR) and homodimers of ζ chains (*olive,* between TCR chains). **B,** Initially after ligand binding, the src-family kinases Lck (associated with CD4 and CD8) and Fyn (cytoplasmic) phosphorylate immunoreceptor tyrosine-based activation motifs (ITAMs) of CD3 and ζ *(black lines)*. **C,** These phosphorylated ITAMs in turn serve as docking sites for the kinase Zap-70 that subsequently phosphorylates the adapter proteins linker of activated T cells (LAT) and (SH2) domain-containing leukocyte protein of 76 kDa (SLP-76), which serve to nucleate the complex containing signaling proteins.

cytoplasmic tyrosines that are phosphorylated by the PTKs activated by the TCR. SLP-76 is a cytosolic adapter protein that is also phosphorylated by these PTKs. Because these tyrosine phosphorylation events create docking sites for other proteins with SH2 domains, when the TCR is engaged, SLP-76 and LAT nucleate a large complex of signaling molecules at the membrane in the vicinity of the activated TCR. This cluster of molecules initiates the signaling cascades that are integrated to result in T-cell activation. Key proteins in this complex are Vav1, a guanine nucleotide exchange factor important for cytoskeletal reorganization; inducible T-cell kinase (ITK), a member of the Tec family of PTKs (a third family of PTKs essential for T-cell activation); adhesion and degranulation-promoting adapter protein (ADAP), an adapter that is a key regulator of integrins to promote T-cell interactions with other cells; PLCγ, the enzyme described earlier that initiates both the calcium and Ras/MAPK pathway in T cells; and growth factor receptor-bound protein 2 (Grb2) and son of sevenless (SOS), two proteins important for activating Ras through a RasGRP independent pathway (Fig. 19-4).

For T-cell immunity to be effective, T cells must possess TCRs that are exquisitely sensitive to specific antigen. Because the TCR is generated through random reassortment of and alteration of gene segments, it is impossible to prevent generation of TCRs that have the potential to respond to self antigens. Although the developmental program of T cells in the thymus provides a mechanism to eliminate most potentially self reactive T cells (see T-Cell Development section later), this process is not 100% effective. Hence, mechanisms exist to prevent mature T cells from responding against normal host tissues. One such mechanism is the requirement for T cells to receive two signals to become activated, one mediated by the TCR and the second through a costimulatory receptor. Although several different T-cell molecules can provide this costimulatory function, the best studied is the surface protein CD28. This additional requirement for T-cell activation helps to prevent autoimmunity because the ligands for CD28, CD80, and CD86 are upregulated on APCs only in the presence of "danger signals" generated largely by bacterial and viral components or in the setting of cellular stress. (The mechanism of how bacterial and viral components signal through Toll-like receptors to activate APCs is described in Chapter 21.)

For CD28 engagement to provide the second signal for T-cell activation, it must also initiate signal transduction pathways (Fig. 19-5). CD28 augments many of the TCR-stimulated pathways described earlier and in particular activates phosphatidylinositol 3-kinase (PI3K), a protein that phosphorylates PIP_2 to form phosphatidylinositol-(3,4,5)-trisphosphate (PIP_3). Although the formation of PIP_3 induces broad changes within cells, the PIP_3 effector molecule that has been studied most intensively is Akt, a serine/threonine kinase responsible for maintaining cell survival and proliferation in a variety of cell types, including T cells, and for altering the metabolism of those cells to favor cell division. The importance of CD28 costimulation of T cells goes beyond its requirement for T-cell activation because engagement of the TCR in the absence of CD28 signaling induces an impaired functional state within T cells termed *anergy* (see Anergy section later in this chapter).

Spatial Coordination of T-Cell Receptor Signal Transduction: The Immunologic Synapse

As the biochemical signaling events that occur after TCR engagement by peptide–MHC became known, investigators sought to define the

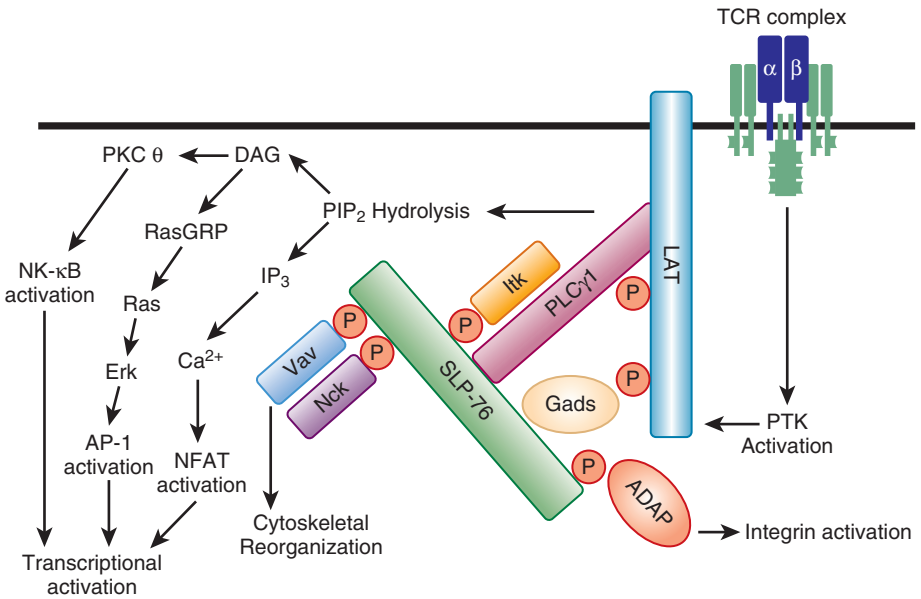

Figure 19-4 INTEGRATION OF T-CELL RECEPTOR (TCR) SIGNALS BY ADAPTER PROTEINS. After engagement of the TCR and activation of protein tyrosine kinases, several hematopoietic specific adapter proteins are phosphorylated, enabling the formation of a multimolecular signaling complex. The transmembrane adapter protein linker of activated T cells (LAT) recruits SH2 domain-containing leukocyte protein of 76 kDa (SLP-76) through the Grb2 family member Gads. This SLP-76 nucleated complex associates with PLCγ1, Itk, Vav1, and adhesion and degranulation-promoting adapter protein (ADAP). After phosphorylation by Itk, PLCγ1 catalyzes the cleavage of PIP_2 into inositol-(1,4,5)-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 induces calcium flux from the endoplasmic reticulum, leading to activation of the transcription factor nuclear factor of activated T cells (NFAT). DAG binds and activates proteins important in signaling such as PKCθ, a kinase whose substrates initiate the activation of the transcription factor nuclear factor κB (NF-κB), and RasGRP, a Ras activating protein that induces activation of Erk and formation of the transcription factor AP-1. Apart from transcriptional changes, T cells also undergo cytoskeletal changes after TCR stimulation mediated in part by Vav1, an activating protein for the actin-modulating protein Rac1, and activation of cell surface integrins, mediated in part by the adapter protein ADAP.

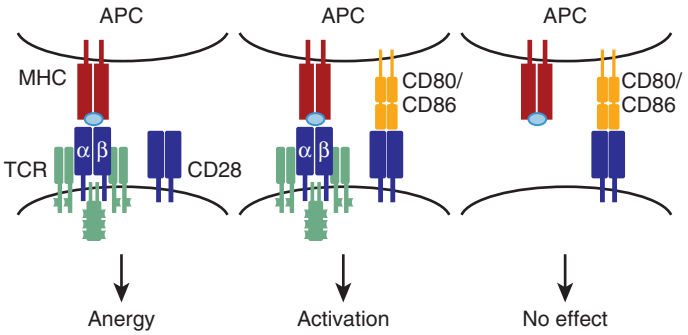

Figure 19-5 TWO SIGNALS ARE REQUIRED TO ACTIVATE T CELLS. T-cell activation requires two signals, one through the T-cell receptor (TCR) and one mediated by a costimulatory molecule, such as CD28. An APC will activate a T cell if it presents appropriate peptide : major histocompatibility complex (MHC) to the T cell and expresses a ligand to engage CD28. If CD28 is engaged without a concomitant TCR signal, the T cell is neither activated nor inactivated. However, if a T cell is stimulated through the TCR in the absence of costimulation through CD28, then it becomes anergic, unresponsive to the initial as well as subsequent stimulations.

topography of the activation events. Sophisticated imaging technologies were applied to visualize the contact site between the APC and the T cell, and this interaction was modeled by visualizing the contact between key receptors on T cells and ligands fixed to a solid support. These studies revealed a stepwise reorganization of the T-cell membrane at the contact site called the immunologic synapse (IS). The first step in IS formation is an interaction between integrins on the surface of the T cell and their ligands on the APC that brings the T cell and APC into close proximity. If a productive interaction occurs between the TCR and peptide–MHC, the next event is clustering of TCRs in the central portion of the developing IS (the so-called central supramolecular activation complex [cSMAC]) with the activated integrins forming the peripheral supramolecular activation complex (pSMAC), a ring around the clustered TCRs. Although ligands on the APC initially direct the formation of the IS, changes within the T cell, including reorganization of the actin cytoskeleton, are also critical for stabilization of this structure. As sophistication of imaging in real time has advanced and with the advent of tools to visualize smaller and smaller numbers of molecules, it has become clear that the IS is a dynamic structure that includes not only the TCR and integrins but also many of the signaling molecules essential for T-cell activation.

When first described, it was assumed that the purpose of the IS was to cluster the TCR together with key signaling molecules to initiate and sustain the T-cell activation program. Recent work indicates that this notion is too simplistic. Evidence suggests that TCR signaling precedes IS formation and that the IS may function to internalize activated receptors, thus terminating their ability to respond. Under other conditions, perhaps when the avidity of the TCR for its ligand is not as great, the IS does appear to maintain contact and allow signaling to occur. Moreover, recent work suggests that another important function of the IS is to focus the release of cytokines from T cells toward other cells of the immune system or materials from the lytic granules of cytotoxic T cells toward their targets, thus enhancing the ability of T cells to exert their appropriate effector functions.

T-Cell Proliferation

The number of naive T cells potentially responsive to any particular peptide antigen (the precursor frequency of the responding population) is quite small, yet a large number of antigen-specific T cells are required to combat pathogens. Accordingly, a consequence of TCR plus costimulatory receptor engagement is the clonal expansion of an activated T cell. One outcome of the second messenger cascades stimulated by the TCR and CD28 is the production of IL-2, an essential cytokine for T-cell proliferation. Another outcome of TCR signaling is upregulation of the high affinity receptor for IL-2, hence making the activated T cell able to respond to local concentrations of this cytokine. Signaling through the IL-2 receptor is necessary for the proliferative response. Similar to the TCR, the IL-2 receptor makes use of cytoplasmic PTKs (in this case members of the Janus kinase [JAK] family) to initiate a cascade of second messengers that lead ultimately to T-cell proliferation.

T-CELL DEVELOPMENT

Protective T-cell immunity requires populating the secondary lymphoid organs with a large number of mature T cells. This population collectively must possess a diverse TCR repertoire capable of recognizing the enormous universe of foreign antigens that will be encountered over life. Because the TCR binds antigenic peptide plus amino acid residues of self MHC molecules, it is essential that only cells with a TCR able to recognize self MHC, albeit with limited affinity, be exported from the thymus to the periphery. It is also critical, however, that the population of peripheral T cells be restricted to those that respond to foreign antigens, and cells possessing TCRs recognizing self peptides plus MHC must not be allowed to complete their developmental program. Ensuring that only those cells with an appropriate TCR mature in the thymus relies heavily on many of the same TCR signal transduction events described earlier.

Unlike most hematopoietic cells that complete the transition from progenitors to mature cells in the bone marrow, T cells develop primarily in the thymus. Experiments in mice demonstrated 50 years ago that neonatal thymectomy results in fatal viral infection, thereby revealing a key role of the thymus in the immune system and paving the way for the identification of the thymus as the site of T-cell development. In the ensuing decades, much has been learned about how progenitor cells enter the thymus and develop into mature T cells.

There are several T lymphocyte lineages. αβ T cells (discussed earlier) are the best studied and most numerous lineage. γδ T cells, another population that possesses an antigen receptor generated through combinatorial rearrangement of gene segments, as well as natural killer T (NKT) cells, a subtype of lymphocytes that has characteristics of both NK and T cells, are also generated in the thymus. It has become clear recently that additional small populations of T cells possessing unique characteristics are produced in the thymus. This chapter focuses primarily on αβ T cells and touches briefly on γδ T-cell development.

Identifying T-cell progenitors is an area of intense investigation because developing tools to manipulate these cells has great therapeutic potential for increasing the speed at which T-cell repopulation may occur after bone marrow transplant. A population of bone marrow-derived thymic settling progenitors (TSPs) that can give rise to mature T-cell populations has been identified. As these cells enter the thymus at the corticomedullary junction, they develop into double-negative (DN) T cells, characterized by lack of expression of the CD4 or CD8 coreceptors (Fig. 19-6). As these early T cells progress though the DN stage, they are further classified as DN1, DN2, DN3, and DN4 stages based on the cell surface receptors they express. During DN1, TSPs lose the ability to differentiate into non-T lineages and begin to proliferate in the deep cortex of the thymus. As the early thymocytes progress to the DN2 phase, they begin to express certain T-cell specific markers, such as Thy-1 (CD90), CD24, and CD25 and initiate TCR gene rearrangement at the TCRγ, TCRδ, and TCRβ loci. Throughout the DN1 to DN3 stages, as the cells migrate from the cortex to the subcapsular zone, interactions between Notch receptors on the developing T cells and specific Notch ligands collaborate with signaling through the IL-7 receptor to regulate differentiation and progression.

During the DN3 stage, rearrangement of TCRγ, TCRδ, and TCRβ loci occurs with maximal efficiency, and initial expression of the TCR proteins these genes encode occurs. From this time onward in T-cell development, the proliferation and survival of the developing thymocytes depend on TCR signals. Two key checkpoints must

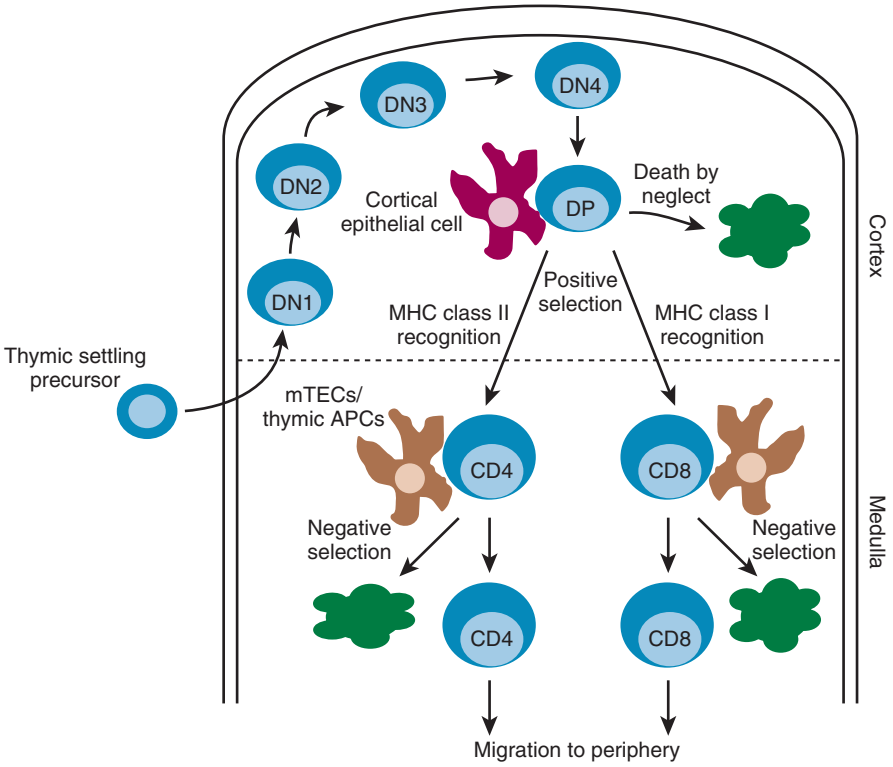

Figure 19-6 T-CELL DEVELOPMENT IN THE THYMUS. Thymic settling precursors (TSPs) from the bone marrow enter the thymus at the corticomedullary junction. These hematopoietic precursors develop into double-negative (DN) thymocytes, at which time they lose the ability to differentiate into non-T lineages, express T-cell markers, and begin TCR gene rearrangement. Developing αβ thymocytes pass through the β-selection checkpoint before progression to the double-positive (DP) stage to ensure that the rearranged TCR proteins are able to transduce signals. DP thymocytes undergo positive selection if their TCR is able to recognize self major histocompatibility complex (MHC) molecules; otherwise, they undergo "death by neglect." Negative selection occurs in the thymic medulla when cells bearing TCRs that bind with strong avidity to self-MHC with self-peptide undergo apoptosis, thereby promoting central tolerance. Mature CD4 SP and CD8 single-positive (SP) cells then emigrate to the periphery.

be passed for full T-cell development to occur. First, upon productive rearrangement of the TCR β locus, the TCRβ protein forms a "pre-TCR" complex with an invariant cytosolic protein designated pre-Tα. This complex engages the TCR signaling machinery, including the PTKs Lck, Fyn, and Syk (a ZAP-70 related PTK) and the adapters SLP-76 and LAT, to initiate the TCR signaling cascade. The resultant biochemical second messengers suppress rearrangement of the other β allele, resulting in "allelic exclusion" or silencing of the nonrearranged allele to ensure each T cell expresses only one TCR specificity. These signals also induce continued T-cell development by promoting rearrangements at the α locus, maintaining cellular survival, initiating a proliferative burst, and inducing expression of CD4 and CD8. For effective signaling to occur, the rearranged β locus must encode a protein that folds correctly and pairs with pre-Tα. Because the rearrangement of the genes that eventually makes up the β chain is a random process, it is often the case that the rearranged allele encodes a dysfunctional protein. In this circumstance, signaling does not occur, and the cell initiates rearrangement at the other β chain allele. Again, if this does not result in a functional protein, no signaling occurs, and the cell undergoes apoptosis. In other cells, a similar rearrangement process occurs in the γ and δ loci. Productive rearrangements of these gene families create a functional, mature γδ TCR that also associates with the TCR signaling complex to propagate signals to trigger further cellular development.

Although the determining factors that result in either γδ or αβ T-cell development have not been fully elucidated, several molecular processes are thought to contribute. The expression of a TCR gene rearrangement product likely plays a role in lineage determination because evidence suggests that developing thymocytes with a functional γδ TCR are often excluded from the αβ cell fate. However, TCR expression is not the only factor in determining lineage fate; cytokine signals and TCR signal strength may also play a role. Experiments have shown that DN2 thymocytes distinguished according to IL-7 receptor expression differentiate into αβ or γδ T cells, with DN2 cells expressing high IL-7 receptor levels preferentially developing into γδ T lymphocytes and those with lower expression more likely to differentiate into the αβ lineage. Other studies have suggested that the strong signals propagated by the γδ TCR compared with those of the pre-TCR complex may promote γδ lineage commitment.

Developing αβ T cells that have passed the first checkpoint demonstrating functional β chain rearrangement transition into the double-positive (DP; $CD4^+CD8^+$) stage and complete TCRα rearrangement to produce a mature αβ TCR heterodimer. The stochastic nature of TCR gene rearrangements guarantees that a significant proportion of cells expressing TCRαβ complexes will not be able to interact with self-MHC proteins and hence would not be stimulated by peptide–MHC complexes in the periphery. DP thymocytes therefore undergo a series of tests, collectively known as *positive and negative selection*, to determine TCR fitness. If the TCR is not stimulated via peptide–MHC complexes presented by thymic APCs, the developing cell undergoes "death by neglect" through apoptosis. Approximately 90% of developing αβ DP thymocytes express a TCR that cannot recognize self peptide–MHC and die by neglect. In contrast, DP thymocytes that interact with self peptide–MHC complexes on thymic cortical epithelial cells with sufficient strength pass this "positive selection" test and are protected from apoptosis.

The MHC specificity of the TCR on a positively selected DP thymocyte influences lineage fate. Cells signaled through a MHC class I–restricted TCR develop into CD8 single-positive (SP; $CD4^-CD8^+$) cells, and those that receive signals via MHC class II–restricted TCRs develop into CD4 SP T cells. The underlying molecular mechanisms governing CD4/CD8 lineage choice is much debated. Predicated on the thought that TCR signals during positive selection result in the termination of either CD4 or CD8 gene transcription, the two classical models of lineage fate are the stochastic selection and instructive models. In the stochastic selection model, TCR signals in a positively selected DP thymocyte randomly terminate either CD4 or CD8 expression. In the instructive model, certain TCR signal qualities, such as strength of signal, direct termination of mismatching coreceptor expression. More recently, a kinetic signaling model has emerged, which proposes that CD4 or CD8 lineage fate is determined by TCR signal duration. Experimental models continue to be tested to fully elucidate the mechanisms underlying lineage fate.

Among the many proteins that are involved in CD4 or CD8 lineage choice are key transcription factors. One such example is Th-POK, a zinc finger protein that is expressed exclusively in $CD4^+$

T cells and not in $CD8^+$ T cells. In transgenic mice, expression of this protein forces the majority of positively selected thymocytes to adopt $CD4^+$ T-cell fate, even those with MHC class I–restricted TCRs. In addition, mice with a spontaneous mutation in Th-POK lack virtually all $CD4^+$ T cells, indicating that its expression is necessary for $CD4^+$ T-cell development. Another important factor is Runx3, a member of the Runx transcription factor family. As DP thymocytes differentiate, Runx3 regulates CD8 differentiation by silencing CD4 transcription, promoting the initiation of CD8 gene transcription, and downregulating Th-POK expression. Additional studies have identified other key transcription factors and signaling proteins important for lineage choice in the thymus, underscoring the complexity of this stage of T-cell development.

Although positive selection ensures that the random combinatorial rearrangement of gene segments results in a TCR that recognizes antigen presented by self MHC proteins, until this point in T-cell development, there is no guard against the emergence of T cells that possess TCRs with high reactivity against self peptides in the MHC binding pockets. Thus, to prevent autoimmunity, there must also be a mechanism to eliminate developing T cells with TCRs expressing these potentially autoreactive specificities. This process is called *negative selection*. Negative selection occurs primarily in the thymic medulla, where thymocytes serially interact with medullary thymic epithelial cells (mTECs) and other thymic APCs, including DCs. At this stage, if thymocytes with TCRs engage peptide–MHC complexes with high affinity, a strong TCR signal initiates apoptosis. Although it is easy to see how this model allows for deletion of developing thymocytes with reactivity against self antigens generated within the thymus itself, it was difficult to imagine how cells with reactivity against antigens known to be expressed outside of the thymus would also be deleted. An explanation for how this occurs came from the discovery of the autoimmune regulator (AIRE) protein. Initially identified as the gene mutated in a rare human autoimmune disorder, autoimmune polyendocrinopathy–candidiasis–ectoderm dystrophy syndrome (APECED), AIRE was later found to be essential for the expression of peripheral tissue specific antigens by mTECs. Although AIRE does not regulate thymic expression of all peripheral antigens, its contribution to the elimination of autoreactive cells is highlighted by the widespread, multiorgan autoimmunity seen in individuals with APECED. Identifying additional mechanisms responsible for thymic expression of tissue-specific genes is an area of active investigation.

Negative selection is one mechanism for development of "tolerance" or immune unresponsiveness to self antigens; however, negative selection is not 100% effective. Hence, other means exist to promote self-tolerance after T cells leave the thymus. One such mechanism relies on development of regulatory T cells (Tregs), which actively interfere with effector T-cell function. Similar to conventional αβ T cells, a subset of Tregs (known as *natural* or *nTregs*) also develops in the thymus. Tregs are characterized by the surface expression of CD4 and CD25 (the α chain of the IL-2 receptor) and depend on the transcription factor forkhead box protein 3 (FoxP3) for their lineage commitment. The gene encoding FoxP3 was originally identified as the causal mutation in a rare human autoimmune disease, immunodysregulation polydendocrinopathy and enteropathy, X-linked (IPEX) syndrome. A mutation in the mouse gene for FoxP3 causes a similar disease (scurfy mice). These naturally occurring loss-of-function mutations demonstrate the necessity for Tregs in maintaining self-tolerance. In the thymus, development into a Treg is enhanced in cells that have high-affinity TCR–peptide–MHC interactions, suggesting that these cells develop specifically to counter autoreactive responses. The exact mechanism that drives these cells to adopt a Treg fate and avoid negative selection during development is being investigated.

The path of developing γδ thymocytes contrasts with that of αβ T-cell development, which is likely related to the function of mature γδ T cells. In the periphery, γδ T cells reside in secondary lymphoid organs with conventional αβ T cells but also are enriched in epithelial tissues of various organs, such as the skin, intestinal epithelium, reproductive tract, and lung. In these distinct settings, the TCR diversity of the γδ T cells is more restricted, suggesting that these subsets may preferentially recognize ligands expressed at these anatomic locations during times of infection or tissue damage.

T-CELL FUNCTION

As T cells leave the thymus, they circulate to secondary lymphoid tissues. Before interaction with their cognate antigen, these cells are designated naïve T cells. As naïve T cells migrate through peripheral lymphoid organs, comprised primarily of the spleen, LNs, and mucosal associated lymphoid tissue, they sample various peptide–MHC complexes on APCs. These APCs include cells residing in the secondary lymphoid organs as well as those in tissues that sample their local environment and then migrate to the secondary lymphoid organs, hence concentrating antigen in these locations. If a naïve T cell does not encounter its specific antigen, it leaves the lymphoid tissue via the lymphatic system to reenter the bloodstream and repeat this process.

When a naïve T cell recognizes its cognate antigen on an APC, a program of proliferation and differentiation transforms the naïve T cell into an effector T cell, now primed to respond rapidly upon encountering its corresponding antigen in the tissues. One important difference between naïve and activated T cells is the cell surface expression of chemokine receptors and integrins. These receptors direct the cell to the appropriate tissue where the effector T cell is needed. Thus, as a part of the T-cell activation process, receptors that direct the naïve T cell in its pathway recirculating between the lymphatic organs and blood vessels are altered for those that direct the activated cell to the tissues, so that the effector T cell reaches the site of pathogen challenge.

$CD4^+$ and $CD8^+$ T cells undergo analogous differentiation processes to acquire functional maturity but play distinct roles in the adaptive immune response to infection. Naïve cells of both lineages are activated through peptide–MHC interaction with their TCRs, and their differentiation is influenced by a combination of signals, including TCR signal strength, costimulation by ligands that interact with other T-cell surface receptors, and the local cytokine environment during antigen encounter. Integration of these signals promotes expression of signature transcription factors and key effector molecules, which allow the mature cell to perform its individualized function. Activated $CD8^+$ T cells possess the machinery to induce death in host cells that express the appropriate peptide within the binding groove of MHC class I, and $CD4^+$ T cells exert their functions through the production of cytokines or through interacting with other immune cell types through direct cell–cell contact after restimulation of their TCR by peptide presented by class II MHC. These so-called "helper" functions marshal and activate other cells of the immune system (Fig. 19-7). Until they encounter peptide–MHC, naïve $CD4^+$ T cells have the potential to develop into one of several effector subsets, including Th1, Th2, Th17, and T follicular helper (Tfh) cells. Additional subsets have been defined recently, but these remain less well characterized and are not discussed in this chapter.

Th1 Cells

Th1 cells activate macrophages, NK cells, and $CD8^+$ T cells to combat intracellular pathogens. Th1 cells also stimulate immunoglobulin (Ig) class switching in B cells for the production of IgG2a antibodies that optimize clearance of viruses and extracellular bacteria. During priming of naïve $CD4^+$ T cells, several factors combine to promote differentiation along the Th1 pathway, including characteristics of the antigen, costimulatory signals from the presenting APC, and the cytokine microenvironment. Several cytokines are implicated in Th1 differentiation, but the two most critical are interferon-γ (IFN-γ) and IL-12. IFN-γ produced by innate immune cells promotes Th1 differentiation, by activating signal transducer and activator of transcription 1 (STAT1), a key signaling molecule that regulates T-bet, one of

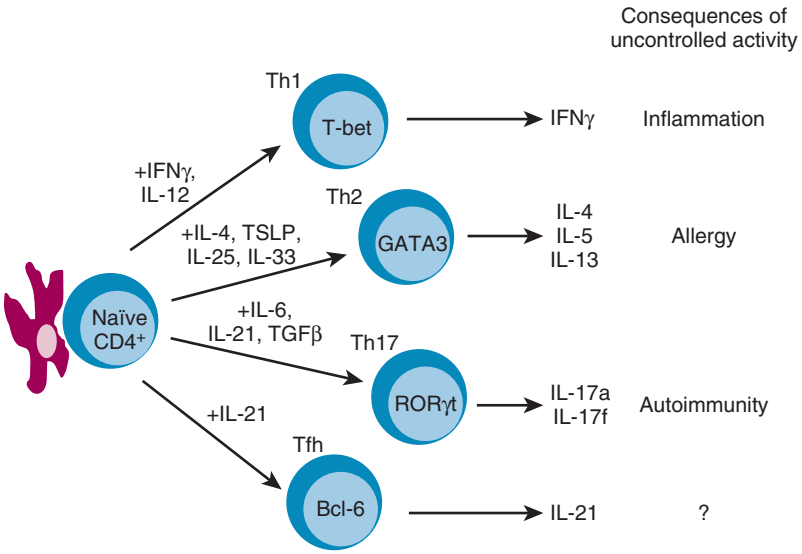

Figure 19-7 DIFFERENTIATION OF $CD4^+$ T HELPER SUBSETS. When activated, $CD4^+$ T cells differentiate into distinct, functionally mature effector subsets. Various factors, including the cytokine milieu, promote the expression of signature transcription factors and effector molecules. $CD4^+$ helper subsets are defined largely by their cytokine production driven by these key transcription factors. Th1 cells are induced by interferon-γ (IFN-γ) and interleukin-12 (IL-12), express the transcription factor T-bet and produce IFN-γ. IL-4 is the primary cytokine that promotes Th2 differentiation. Th2 cells are characterized by expression of GATA-3 and production of IL-4, IL-5, and IL-13. Naive $CD4^+$ cells that are activated in the presence of IL-6 and IL-21 differentiate into Th17 cells, typified by the expression of ROR-γt and production of the IL-17 family of cytokines. T follicular helper (Tfh) cell differentiation is mediated by IL-21. These cells are characterized by the transcription factor Bcl-6 and production of IL-21. If $CD4^+$ helper differentiation and activity are not adequately controlled, imbalanced responses can lead to pathologic conditions.

the signature transcription factors associated with Th1 cells. IL-12, produced by activated APCs and other innate immune cells, acts through a separate STAT4-dependent pathway to promote IFN-γ production. IL-12 also signals to upregulate its own receptor and the IL-18 receptor, thereby allowing IL-18 to act in concert with IL-12 to promote IFN-γ production, thus creating a "feedforward" cycle to amplify the Th1 response.

T-bet, a T-box family member, is the key transcription factor associated with Th1 differentiation and function. T-bet–deficient T cells are defective in their ability to differentiate into Th1 cells either in vitro or in vivo, and T-bet–deficient mice are unable to control *Leishmania major* infection, a well-characterized intracellular pathogen model that depends on the characteristic Th1 cytokines for its clearance. Although T-bet is considered the "essential" factor that directs Th1 lineage determination, other transcription factors, such as Runx3 and Hlx, are important for optimal Th1 function.

After differentiation, Th1 effector cells are characterized by production of proinflammatory cytokines such as IFN-γ and tumor necrosis factor α (TNF-α) that stimulate macrophages, NK cells, and $CD8^+$ T cells to promote pathogen clearance. It is clear, however, that Th1 function must be balanced. Evidence from both animal models and human patients indicates that overexuberant Th1 responses drive inflammatory conditions and may lead to tissue destruction.

Th2 Cells

Th2 cells are critical for the immune response against extracellular parasites, such as helminths, through production of IL-4, IL-5, and IL-13. At initial sites of parasitic infection, epithelial cells of the target organs, including the skin, lungs, and intestines, and resident cells of the innate immune system sense parasite-derived products and produce Th2-inducing cytokines, including thymic stromal lymphopoietin (TSLP), IL-4, IL-25, and IL-33. These cytokines then act on innate immune cells, including basophils and DCs, as well as directly on naïve $CD4^+$ cells to promote Th2 differentiation.

Recent work has provided insight into how cytokine signaling, particularly IL-4 signaling, promotes Th2 differentiation. Through interaction with its receptor, IL-4 activates STAT6. STAT6 plays a vital role in Th2 differentiation, as evidenced by the profound reduction in development of this lineage in *Stat6*-deficient mice. STAT6 activation leads to its nuclear translocation and subsequent induction of the transcription factor GATA-3, which, similar to T-bet for Th1 cells, is considered the master regulator of Th2 differentiation. GATA3 regulates Th2 cytokine production by binding and activating the "Th2 locus," which includes the genes encoding IL-4, IL-5, and IL-13. When GATA3 function is abrogated, Th2 differentiation is virtually absent both in vitro and in vivo. In mature differentiated Th2 cells, GATA3 deficiency results in loss of IL-5 and IL-13 production. GATA3 is both necessary and sufficient for Th2 differentiation because forced expression either by retroviral constructs or transgenic expression promotes Th2 differentiation and represses Th1 differentiation. Repression of Th1 development is as least partially through GATA3-dependent inhibition of STAT4, thus interfering with *Ifng* gene transcription.

TCR signal strength also is involved in determining if a naïve T cell will differentiate into a Th1 or Th2 cell. Studies in mice using altered peptide ligands that have decreased affinity for particular TCRs and experiments using limiting dose of antigen have demonstrated that diminished TCR stimulation promotes Th2 cell differentiation. Differences in costimulation also affect Th2 pathway differentiation. Mice deficient in CD28 or CD80/CD86 have a more pronounced defect in Th2 responses, suggesting that these molecules may play a greater role in promoting Th2 differentiation than Th1 differentiation.

IL-4 produced by mature Th2 cells acts in a positive feedback loop to promote further Th2 cell differentiation in naïve T cells as they encounter antigen. Th2-derived IL-4 also mediates IgE class switching in B cells. Soluble IgE binds to and crosslinks its high-affinity receptor FcεRI on basophils and mast cells, promoting production of histamine and serotonin as well as several cytokines, including IL-4, IL-13, and TNF-α. IL-5 produced from Th2 cells recruits eosinophils, and Th2-derived IL-13 promotes both the expulsion of helminths during parasitic infection and the induction of airway hypersensitivity.

Th2 responses are critical for immunity against extracellular parasites, but excessive Th2 responses are associated with the pathologic conditions of allergy and airway hypersensitivity. The recent increase in asthma in the developed world has been linked to an imbalance of Th subsets with skewing towards "Th2-ness" in the population. Additional work is necessary to more firmly establish a molecular immunologic link to the epidemiology of these diseases.

Th17 Cells

The original description of Th1 and Th2 cells, indicating that not all mature $CD4^+$ T cells were alike, led to the search for other $CD4^+$ subsets. One such cell type was identified after unexpected results were observed in experimental autoimmune disease models. For many years, mouse models of multiple sclerosis and rheumatoid arthritis were thought to be dependent on excessive Th1-driven inflammation. Because IL-12 is a key factor in Th1-mediated responses, blocking IL-12 signaling was predicted to ameliorate experimental autoimmunity. IL-12 is a heterodimeric protein that includes a larger (p40) and

smaller (p35) subunit. Experiments in mice in which p40 was deleted revealed the expected result with marked resistance to autoimmunity. Surprisingly, however, mice lacking p35 still exhibited disease, although IL-12 function was abrogated. An explanation for this apparent paradox emerged as it was learned that the p40 subunit was not unique to IL-12 but also dimerized with p19 to form the cytokine IL-23. The hypothesis then arose that IL-23 was the critical driver of autoimmunity in the mice, and IL-23–deficient animals were resistant to disease. These findings led to further studies that revealed IL-23 to be critical for the generation of another Th subset, later designated Th17 because of the production of its signature cytokine IL-17. Extensive analyses of IL-17 and the cells that produce this cytokine demonstrate that Th17 cells are important for the control of extracellular bacterial and fungal infections. With excessive activity, however, these cells also appear to play an important role in autoimmune diseases through the production of proinflammatory cytokines, including IL-17A, IL-17F, IL-21, and IL-22.

Although IL-23 is a key regulator of Th17 cells, the IL-23 receptor is not expressed on naïve $CD4^+$ cells and hence could not explain the differentiation of cells into the Th17 subset. Subsequent studies demonstrated that the combination of transforming growth factor-β (TGF-β) with either IL-16 or IL-21 induces Th17 differentiation in mice; however, in human cells, IL-6, IL-1 and IL-23 are sufficient to induce Th17 differentiation. Studies are ongoing to clarify the differential cytokine requirements for Th17 differentiation in mice and humans. The cytokines that are key mediators of Th17 differentiation and survival, including IL-6, IL-21, and IL-23, all activate STAT3. The critical role of this STAT family member was demonstrated in murine studies, when its deletion abrogated the ability of T cells to undergo Th17 differentiation. In humans, the importance of STAT3 was highlighted when it was identified as the genetic mutation present in many patients with hyper-IgE syndrome (HIES, or Job syndrome). HIES is a rare immunodeficiency syndrome characterized by recurrent staphylococcal skin abscesses, elevated serum IgE, and pneumatocele-forming pneumonias. HIES patients with STAT3 mutations have an impaired ability to form Th17 cells, which may explain part of their immunodeficiency. STAT3 regulates expression of many cytokine and cytokine receptor genes involved in Th17 generation or function, including IL-17A, IL-17F, IL-21, IL-21R, and IL-23R.

STAT3 is also important for induction of the signature Th17 transcription factor ROR-γt, which is a member of the retinoic acid–related orphan receptor family. In naïve $CD4^+$ cells, ROR-γt induces IL-17 gene transcription and promotes expression of the IL-23 receptor. Overexpression of ROR-γt induces Th17 differentiation, but deficiency of ROR-γt only partially affects Th17 cells in vivo because of expression of the related transcription factor RORα, which is also expressed in T cells and is induced by IL-6/TGF-β in a STAT3-dependent manner. Cells deficient in both ROR-γt and RORα lose the ability to undergo Th17 differentiation, both in vitro and in vivo.

Th17 cells are induced during the response to extracellular bacteria and fungi, including *Klebsiella pneumoniae, Bacteroides* spp., and *Candida albicans*. Indeed, some patients with chronic mucocutaneous candidiasis have been shown to have mutations in IL-17F and the IL-17 receptor genes. Excessive Th17 cell function also plays a role in autoimmune disease, such as rheumatoid arthritis, psoriasis, and Crohn disease.

Tfh Cells

In addition to Th1, Th2, and Th17 subsets, naïve $CD4^+$ cells develop other functions dependent on the cytokines produced. Examples include newly described Th9, Th22, and Tfh cells. This latter subset enhances the humoral immune response by providing help to B cells during germinal center reactions. Tfh cells express high levels of CXCR5, the receptor for the chemokine CXCL13. The expression of CXCR5 allows differentiating Tfh cells to migrate from the T-cell zone to the CXCL13-rich B-cell follicle, thereby allowing Tfh cells to interact with B cells and exert their function. In addition to CXCR5 expression, other signals, such as TCR signal strength and costimulatory molecules, are important for Tfh differentiation. A recent study using adoptive transfer of naïve $CD4^+$ cells expressing high- and low-affinity transgenic TCRs demonstrated that high-affinity TCR interactions preferentially developed into the Tfh subset. Tfh cells have higher expression of multiple costimulatory molecules, including CD40L, ICOS (inducible costimulator), and OX40, than other T-helper subsets. Because costimulatory molecules enhance B-cell differentiation, the higher expression of these molecules on Tfh cells is hypothesized to positively correlate with the enhanced ability to facilitate B-cell antibody production. It appears that the expression of costimulatory molecules on Tfh cells is not only important for their function but also for their development or maintenance (or both) because both mice and humans deficient in ICOS have fewer Tfh cells with reduced germinal center formation.

Similar to other $CD4^+$ helper subsets, Tfh programming depends on a signature transcription factor, in this case Bcl-6 (B-cell lymphoma 6 protein). In Tfh cells, Bcl-6 acts as a transcriptional repressor. Studies using complementary methods of T cell–specific Bcl-6 deficiency and overexpression demonstrated that Bcl-6 expression in T cells is both necessary and sufficient for Tfh differentiation in vivo.

$CD8^+$ Cytotoxic T Cells

The principal function of $CD8^+$ cytotoxic T cells (CTLs) is to kill host cells that have been infected with pathogens or that have undergone deleterious changes, such as malignant transformation. Similar to $CD4^+$ cells, naïve $CD8^+$ cells initially encounter peptide antigen and MHC on the surface of APCs in the secondary lymphoid organs. However, unlike $CD4^+$ cells, which are stimulated by class II MHC alleles on the APCs, $CD8^+$ cells are engaged by class I MHC plus peptide. For many years, it remained unclear how APCs, which acquire peptide antigens largely by engulfing materials generated outside of the cell, are able to present MHC class I–restricted peptides, which typically are generated within the cell (see earlier discussion). This mystery was solved with the description of "cross presentation," a mechanism by which APCs present engulfed antigens on both class I and class II alleles. Thus, tissue-resident phagocytic cells ingest virally infected or malignantly transformed host cells, degrade the ingested material, and present the peptide antigens in the binding grooves of both class I and class II MHC alleles. These activated phagocytic cells then migrate to the LNs, where they encounter recirculating naïve $CD8^+$ cells. TCR engagement of foreign peptide–MHC class I complexes triggers activation of the $CD8^+$ T cells and initiates CTL differentiation. As part of its activation program, the CTL changes its expression of integrins and chemokine receptors so that it can leave the circulation and enter the tissues, looking for host cells displaying the same antigen that induced CTL activation by the APC in the LN.

After an appropriate target cell has been identified in the tissues, the CTL is again stimulated through its TCR, this time by the peptide–MHC class I combination on the target cells. A structure similar to the IS forms between the CTL and the target cell. The CTL contains specialized granules that are transported to the contact site between the CTL and target. These granules are modified lysosomes that contain effector proteins, including perforin, granzymes, and granulysin. Perforin facilitates the entry of the granzymes into the cytosol of the target cell. The granzyme family, consisting of granzymes A, B, H, K, and M, are proteases that degrade host cell proteins. Granzyme B is the most well-studied family member and is known to cleave caspase 3, activating a proteolytic cascade leading to DNA degradation and apoptosis of the target cell (Fig. 19-8). Granzyme B also promotes cell death in a caspase-independent manner through cleavage of the proapoptotic protein Bid, promoting its migration to and disruption of the outer mitochondrial membrane, resulting in the release of cytochrome c. CTLs also produce cytokines, including IFN-γ, TNF-α, and IL-2. IFN-γ acts to inhibit viral replication in the affected tissues and induces increased class I MHC expression, hence improving the ability of cells to stimulate the TCR on CTLs. IFN-γ synergizes with TNF-α for macrophage activation.

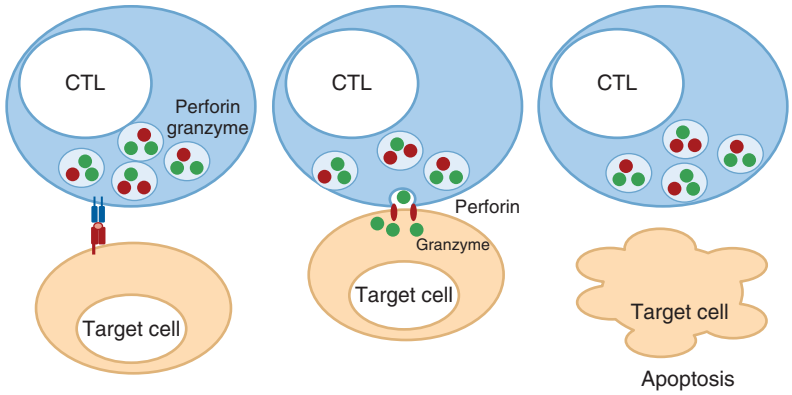

Figure 19-8 $CD8^+$ CYTOLYTIC FUNCTION. Cytotoxic $CD8^+$ T cells function primarily to kill host cells that have been infected by intracellular pathogens or that have undergone malignant transformation. After naïve $CD8^+$ cells encounter peptide-major histocompatibility complex (MHC) class I plus costimulation in secondary lymphoid organs, these activated cytotoxic T cells (CTLs) leave the circulation and enter the tissues. There, upon interaction with a target expressing that same peptide-MHC class I, a CTL forms a lytic synapse, similar to the immunologic synapse (IS), with the target. Cytoplasmic granules containing perforin and granzymes congregate at the synapse, and granule contents are exocytosed into the cleft between the CTL and its target cell. Perforin molecules facilitate entry of the cytolytic molecules into the target cells and granzymes act to promote apoptosis of the target cell.

The transcription factors important for $CD8^+$ T-cell effector differentiation include two members of the T-box family, T-bet and Eomesodermin (Eomes). Initially identified as the master Th1 determining transcription factor in $CD4^+$ cells, T-bet also plays an essential role in $CD8^+$ effector cell differentiation. Recent work has shown that T-bet expression is highest in short-lived effector cells and lower in $CD8^+$ T cells destined to become memory cells (see later discussion), suggesting that a gradient of T-bet expression controls the balance between different $CD8^+$ effector fates. Eomes cooperates with T-bet in CTL function, and cells deficient in both factors are unable to generate CTLs in response to viral infection.

MATURATION OF T CELL–MEDIATED IMMUNITY

T-Cell Memory

The activation of naïve T cells does not complete their maturation process; instead, it is the starting point for the changes that result in T cell–mediated immunity. At the initiation of an infection, individual antigen-specific T cells become activated and expand robustly to combat the pathogen. As the pathogen is eradicated, the large population of activated T cells must contract dramatically to ensure homeostasis of the immune system. However, a discrete but relatively small population of antigen-specific T cells persists. These long-lived T cells have properties distinct from naïve or activated T cells, including self-renewal through homeostatic proliferation and the ability to rapidly proliferate and regain effector function upon reexposure to antigen. These are the cardinal features of cell-mediated immunologic memory.

Immunologic memory refers to the observation that after an initial exposure and mounting of an effective immune response to a pathogen, subsequent interactions with that pathogen elicit rapid and robust T-cell activation with more efficient clearance of the pathogen. Memory is the foundation of vaccination because immunization with pathogen-specific antigens induces a memory response so that the first exposure of the host to the pathogen itself results in a rapid, effective response, thus abrogating signs and symptoms of the infection.

Within days of infection, subsets of activated effector T cells can be identified with different cell fates: those that are terminally differentiated and those that have the potential to develop into memory cells. How memory cells develop from naïve T cells is a subject of ongoing debate, and several models have been proposed. In one model, memory T cells are thought to develop from a broad pool of activated effector T cells with most effector cells undergoing apoptosis and others surviving to provide memory. A second model suggests that when activated, naïve T cells randomly differentiate into either effectors or memory cells. Most recently, it was postulated that memory cells develop from naïve cells at the first contact with peptide–MHC complexes but not in a random fashion. Instead, asymmetric partitioning of various proteins into the daughter cells during the first cell division determines effector versus memory lineage formation.

Similar to effector T cells, there are different subsets of memory cells. The two main classes are effector memory and central memory T cells. Effector memory T cells, characterized by loss of expression of LN homing molecules CD62L and CCR7, rapidly produce cytokines in response to restimulation with previously encountered antigen, thereby allowing for rapid responses to invading pathogens. These cells preferentially reside in nonlymphoid tissues, such as lung and intestinal mucosa, which are frequently sites of pathogen entry. In contrast, central memory cells express high levels of CD62L and CCR7, are more prevalent in lymphoid tissues, and mount a robust proliferative response after reencountering antigen.

As with differentiation of naïve T cells into efficient effectors, cytokines play an important role in memory T-cell development and maintenance. IL-2 is essential for initial memory cell differentiation, and IL-7 and IL-15 are crucial for memory cell persistence. Other signals, such as the strength of antigenic and inflammatory signals during T-cell activation, also influence memory cell development and maintenance. An important consideration for memory development is cell–cell interactions because $CD4^+$ T cells are required during initial priming of $CD8^+$ cells for development of fully functional $CD8^+$ memory cells. A number of infectious disease models have demonstrated that in the absence of $CD4^+$ T-cell help, fewer $CD8^+$ memory T cells are maintained, and those that do persist are of the central memory phenotype. Although great progress has been made elucidating the molecular underpinnings of immunologic memory, much remains to be learned. As additional discoveries are made, it is anticipated that new approaches will develop to improve vaccines against infectious agents and to harness host T-cell responses to combat tumors.

T-Cell Exhaustion: An Aborted T-Cell Response

Under most circumstances, acute infection results in the expansion of T lymphocytes specific for the inciting pathogen, clearance of the pathogen, and the development of memory T cells able to more effectively clear that pathogen if the host is reexposed. However, some pathogens cannot be efficiently cleared from infected hosts and persist throughout the lifetime of the organism despite the formation of pathogen-specific T cells. Examples of such pathogens include human immunodeficiency virus and hepatitis viruses B and C. These persistent infections result in chronic antigen exposure, which instead of continuing to induce productive T-cell responses leads to the generation of "exhausted" T cells that have lost the ability to kill and produce cytokines capable of controlling the infection. The development of T-cell memory and the exhaustion response are initiated in similar ways, with the formation of cells that are capable of responding to antigen challenge through proliferation and the secretion of cytokines. However, during exhaustion, the persistence of pathogen causes T cells to become increasingly ineffective in response to stimulation. At early time points in this process, exhausted $CD8^+$ T cells lose the ability to secrete IL-2 or TNF-α and cannot induce cytolysis of infected host cells. At later time points, $CD8^+$ T cells become completely unresponsive and ultimately undergo apoptosis.

Concurrent with the loss of functional responses, exhausted cells upregulate inhibitory cell surface receptors. The best-studied of these inhibitory receptors is programmed death 1 (PD-1), which binds its ligand, PD-L1, expressed on activated macrophages and other APCs. Engagement of PD-1 dampens the T-cell response, likely by recruiting phosphatases that oppose the PTKs necessary for T-cell activation. PD-1 is normally expressed on T cells after initial activation, likely to prevent excessive responses, and is then downregulated as T cells acquire a memory phenotype after the pathogen clearance. Exhausted T cells, however, continue to express this inhibitory receptor. Early during exhaustion, PD-1 blockade reversed T-cell exhaustion in experimental models; however, other inhibitory receptors are expressed on these cells. Blockade of PD-1 with these other receptors has been shown to improve T-cell responsiveness even at later stages of exhaustion. Better understanding of the biology of PD-1 and other key inhibitory receptors and how these molecules interfere with T-cell responses will guide the development of new therapies to combat pathogens that are difficult to eradicate.

INHIBITION OF T CELL–MEDIATED IMMUNITY

Efficient signaling through the TCR and other cell surface molecules is required for initial T-cell activation. Similarly, appropriate maturation of the T-cell response to generate effectors and memory cells is critical for adequate responses to pathogens. Because of the potential for activated T cells to damage host tissues, an integral aspect of the immune system is to negatively regulate T-cell activities. The mechanisms for inhibiting T-cell responses are critical for the prevention of inappropriate activation of naïve T cells at the initiation of an immune response, for limiting the robustness of an appropriate T-cell response as effector cell functions are developed, and for terminating the T-cell response when an antigenic challenge has been met. This section discusses examples of how T-cell activation is modulated at each of these three critical steps of T-cell immunity.

Prevention of Inappropriate Initiation of T-Cell Responses

Given the enormous power of immune effector cells to damage tissues, it is essential that the immune system be nonreactive (tolerant) to self. As already described, T-cell tolerance is achieved centrally through the requirement to pass selection checkpoints during thymic development. However, negative selection in the thymus is not sufficient to eliminate all cells with potential autoreactivity, and some T cells bearing TCRs that may respond to self antigens are exported from the thymus to the periphery. Mechanisms are in place to prevent these cells from becoming active effectors as they encounter antigen. Two such mechanisms are anergy, a process by which T cells limit their own responsiveness based on engagement of particular cell surface receptors (a cell intrinsic path to inactivation), and the action of Treg cells, which instruct potential effectors to remain quiescent.

Anergy

One means to limit T-cell responses against host tissues is a process of self-inactivation termed *anergy*. As noted earlier, T cells require signaling through both the TCR and the costimulatory receptor CD28 to become activated (see Fig. 19-5). Stimulation of the TCR alone in the absence of costimulation through CD28 produces T cells that fail to secrete IL-2 or upregulate high-affinity receptors for this cytokine and hence fail to clonally expand. Cells that have been rendered anergic fail to respond to subsequent stimulation even if ligands for both the TCR and CD28 are available. This two signal requirement ensures that only APCs activated by pathogens or other "danger signals" can initiate an immune response because CD80 and CD86, the ligands for CD28, are upregulated only in activated APCs. Thus, under circumstances of pathogen invasion, APCs present peptide antigens to T cells in addition to CD28 ligands. In the absence of an immune challenge, APCs express only low levels of CD80 or CD86. If a T cell encounters an APC that presents a stimulatory peptide–MHC complex but lacks sufficient expression of CD28 ligands, the T cell does not become activated. In this situation, the absence of ligands for CD28 implies that there is no "danger" and that the antigen being recognized is derived from a self protein. The result of such an encounter leaves the T cell in an anergic state, refractory to activation even in the face of subsequent TCR stimulation by an activated APC.

The role of anergy in human immunology remains unclear because investigators have largely utilized in vitro models systems and animal models. However, several lines of evidence indicate that there are self antigen–reactive T cells that remain quiescent in normal human hosts. The biochemical basis of anergy also remains incompletely understood, but intriguing models suggest that an imbalance between the strength of Ras versus calcium signaling may be crucial. In this paradigm, it is the activation of calcium-dependent transcription factors, such as NFAT, in the absence of transcription factors activated by Ras signaling, such as AP-1, that confers an anergic state. Although anergy is classically thought to persist indefinitely, under some circumstances, there is apparent plasticity because exposure of T cells to high concentrations of IL-2 can improve functional responses in previously anergic cells. Thus, the physiologic importance of anergy in limiting endogenous T-cell activation and preventing autoimmunity and whether there are times when anergy must be reversed for appropriate immune responses are areas of active investigation.

Regulatory T Cells

Tregs are a subset of $CD4^+$ T cells that suppress the proliferation and cytokine production of activated T cells whose TCRs have been engaged by peptide–MHC, even in the presence of costimulation. Hence, as opposed to anergy, which operates in a cell intrinsic fashion, Tregs block responsiveness in *trans* by modulating responses of other cells. Tregs arise in two ways: "natural" Tregs (nTregs) that acquire function during development in the thymus (described earlier), and "inducible" Tregs (iTregs) that are generated through the differentiation of naïve $CD4^+$ T cells in the periphery. Both natural and inducible Tregs are characterized by expression of the key transcription factor FoxP3 and by surface expression of CD25, a subunit of the receptor for IL-2.

As noted, multiple steps and checkpoints occur during the development of T cells in the thymus. After reaching the DP stage, T cells test their TCR for reactivity against peptide–MHC complexes

presented by thymic APCs and epithelial cells. Cells bearing TCRs with no reactivity undergo apoptosis (failed positive selection) as do cells with very strong TCR reactivity (through negative selection). Only cells whose TCRs have moderate affinity for peptide–MHC continue to mature. Within this continuum of permitted reactivity, cells with TCRs exhibiting the highest affinity for peptide–MHC are induced to express FoxP3 and develop into Tregs. In the periphery, these cells respond to TCR stimulation by diminishing the response of "conventional" T effector cells, thus downregulating immune responses.

iTregs act similarly to nTregs, but these cells do not leave the thymus poised to have suppressive function. Instead, these cells arise from naïve T cells that encounter antigen in the secondary lymphoid structures. Similar to other $CD4^+$ subsets, iTregs are induced based on the prevailing cytokine conditions and what receptor–ligand interactions predominate during this initial antigen encounter. Regardless of whether they arise in the thymus or are induced in the periphery, Tregs exert their immunosuppressive functions on a variety of immune cells, including $CD4^+$ and $CD8^+$ T cells, DCs, B cells, macrophages, and NK cells, within their microenvironment. Tregs mediate these immunosuppressive effects through the secretion of suppressor cytokines such as IL-10 and TGF-β, the consumption of local concentrations of IL-2, and the induction of apoptosis or cell cycle arrest through direct cell-to-cell contact (Fig. 19-9).

Limiting T-Cell Responses After Stimulation by Foreign Antigen

Even when stimulated appropriately to combat an invading pathogen, it is essential to limit T-cell activation. Unchecked T-cell effector functions present a danger to the host through production of proinflammatory cytokines that recruit other cells of the immune system and through direct damage of self tissues. T-cell effector functions are limited by modulating the T-cell activation pathways through activation of signaling molecules that counter the second messengers stimulated by TCR engagement; through inducible expression of cell surface receptors that compete with activating receptors on the T cell; or by targeting key activating proteins for destruction, thus limiting their ability to promote T-cell effector function. Additionally, the local environment in which the T cell exists may change, with cell extrinsic factors (e.g., inhibitory cytokines) becoming available to dampen T-cell responses (Fig. 19-10).

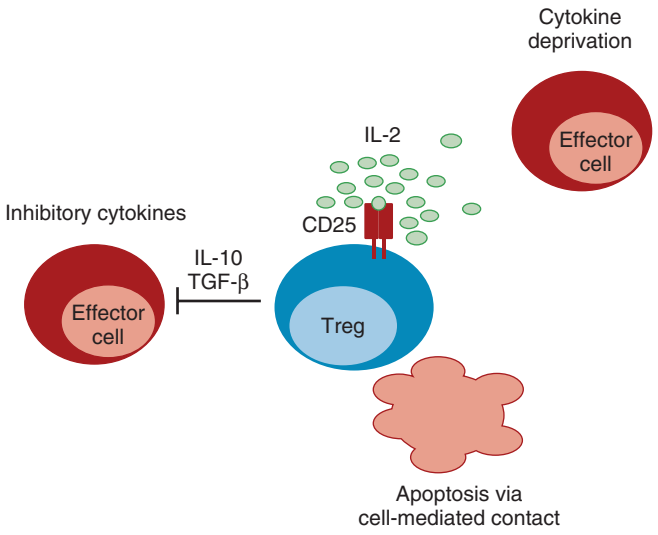

Figure 19-9 T-REGULATORY CELL (Treg) ACTIONS. Tregs act to suppress other T cells through a multitude of mechanisms, including the secretion of suppressor cytokines interleukin-10 (IL-10) and transforming growth factor β (TGF-β), consumption of local concentrations of IL-2 and induction of cell cycle arrest or apoptosis.

Limitation of T-Cell Activity From Cell-Intrinsic Components

Protein Tyrosine Phosphatases

As already noted, the most proximal known biochemical event to occur after engagement of the TCR by peptide–MHC results is activation of PTKs, including Lck and Zap-70, enzymes central to the T-cell activation program. Thus, one means to limit TCR signaling is to oppose the activating PTKs with deactivating protein tyrosine phosphatases, reversing the phosphorylation events that drive T-cell activation. Several such phosphatases have now been identified, including SH2 domain-containing phosphatase-1 (SHP-1) and protein tyrosine phosphatase, nonreceptor type 1 (PTPN1). Although the direct targets of these phosphatases have yet to be demonstrated conclusively, there is increasing evidence in murine systems that they are important for control of T-cell activation as well as for regulating function of other cells of the immune system. Experiments show that SHP-1–deficient T cells demonstrate enhanced proliferation and cytokine production after stimulation compared with wild-type cells. These cells also show prolonged phosphorylation of TCR signaling molecules, consistent with a role for SHP-1 in reversing these events. Overexpression of SHP-1 within T-cell lines inhibits TCR-mediated signaling events. Furthermore, SHP-1 is recruited into the IS after

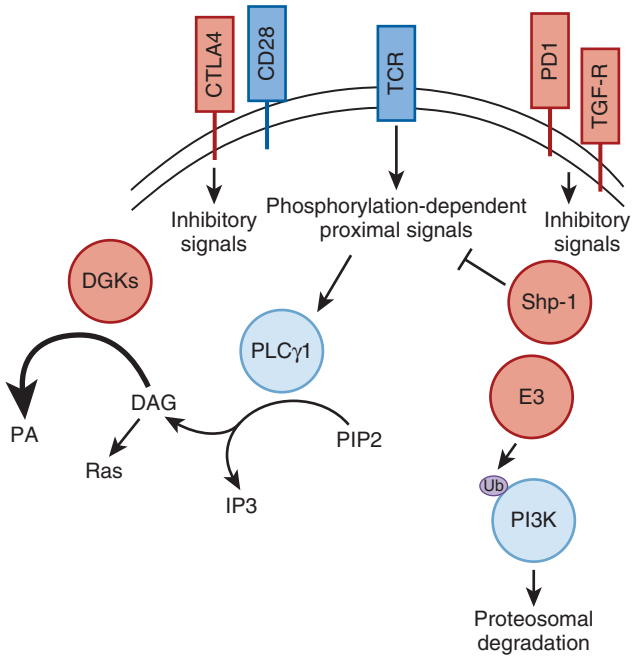

Figure 19-10 INHIBITORY PATHWAYS IN T CELLS. Negative influences on T cells and T-cell receptor (TCR) signaling take place at multiple levels within T cells and are crucial for the prevention of autoimmunity. Examples (indicated in *red*) include the protein tyrosine phosphatase 2 domain-containing phosphatase-1 (SHP-1) that opposes early phosphorylation events mediated by kinases after TCR activation; E3 ubiquitin ligases such as cbl-b that ubiquitinate key signaling mediators, such as PI3K, resulting in proteosome-mediated degradation; and diacylglycerol kinases (DGKs), which terminate TCR signaling by metabolizing signaling intermediates such as diacylglycerol (DAG). Cytotoxic T lymphocyte antigen-4 (CTLA-4), a T-cell surface receptor upregulated after activation, also induces T-cell inhibition, both by sequestering B7 away from the activating costimulatory molecule CD28 and by transducing its own inhibitory signals after B7 binding. Other well-established inhibitory T-cell surface receptors are PD-1, which is expressed under prolonged antigenic stimulation or "exhaustion", and the transforming growth factor β receptor (TGFβ-R), a receptor for one a cytokine key for Treg-mediated suppression.

engagement of the TCR, thus providing an appropriate physical localization for SHP-1 to directly engage targets of the TCR-stimulated PTKs. SHP-1 inhibitory activity appears to be crucial in vivo because mice that lack functional SHP-1 develop fatal autoimmunity, likely because of alterations of function of both innate and adaptive immune cells. Accumulating evidence indicates that other phosphatases are also critical for interfering with T-cell activation, both in animal models and more recently in studies of human patients. Polymorphisms in the genes encoding several protein tyrosine phosphatases, including CD45 and *PTPN22*, align with susceptibility to human immune-mediated disorders. These intriguing findings are being pursued actively by a number of laboratories to uncover the molecular basis of how these phosphatases exert their control on immune cell function.

CTLA-4

A second strategy to limit T-cell activity is through the induced expression and activation of inhibitory cell surface receptors (e.g., cytotoxic T lymphocyte antigen-4 [CTLA-4]). As already discussed, activation of T cells requires two independent signals, one through the TCR and a second through a costimulatory receptor such as CD28. Several days after initial T-cell activation, however, another member of the CD28 superfamily, CTLA-4, becomes upregulated on T cells. CTLA-4 differs from CD28 in that instead of serving as an essential costimulatory receptor, engaged CTLA-4 actively interferes with T-cell activation. Moreover, CTLA-4 binds CD80 and CD86 with much higher affinity than CD28, thus sequestering these key ligands away from CD28. The importance of CTLA-4 in controlling immune reactions was highlighted in a study of CTLA-4–deficient mice, which were found to die from autoimmune disease at 3 to 4 weeks of age. Targeting CTLA-4 with blocking antibodies to augment T-cell responses is being tested as a therapeutic strategy for human cancer treatment. Conversely, providing soluble CTLA-4 to patients with autoimmunity has been shown to be effective at blocking T-cell activation, presumably by interfering with the ability of CD28 to bind to its ligands, hence delivering an anergizing signal to T cells.

E3 Ubiquitin Ligases

T-cell receptor signaling is also limited through the targeted destruction of proteins required for TCR signal transduction. E3 ubiquitin ligases are a class of proteins that target intracellular proteins for degradation by the proteosome, the large multisubunit cytosolic complex essential for protein turnover. In T cells, several E3 ubiquitin ligases target components of TCR signal transduction for degradation after TCR activation. These include c-cbl, Itch, and Casitas b-lineage lymphoma-b (cbl-b). As with other negative modulators of TCR signaling, genetic deletion of E3 ubiquitin ligases, either alone or in combination, results in dysregulation of immune function or the development of frank autoimmune disease in mice. The targeted degradation of crucial signaling modulators after T-cell activation thus serves as an additional physiologic mechanism to limit T-cell responses.

Diacylglycerol Kinases

Intrinsic cellular components limit T-cell activity through degradation of second messengers of T-cell signal transduction, such as metabolism of diacylglycerol (DAG) by diacylglycerol kinases (DGKs). As described earlier, engagement of the TCR results in the activation and recruitment of PLCγ1 that cleaves PIP_2 into the second messengers DAG and IP_3. DAG levels are regulated in T cells through the activity of DGKs that metabolize DAG to terminate its ability to transduce signals. Two DGK isoforms, DGKα and DGKζ, are important for limiting TCR signaling because deletion of either in mice results in enhanced proliferation and cytokine production after TCR stimulation. Moreover, deletion of DGKα leads to impaired induction of T-cell anergy. Mice deficient in either isoform of DGK do not develop overt autoimmune disease, likely because of the functional overlap of these two isoforms. However, enhanced functional responses to viral infection and tumors have been reported in DGK-deficient T cells, defining an important role for DGKs in limiting immune responses.

Limitation of T-Cell Activity From Cell-Extrinsic Components

Extrinsic factors also help limit the function and activation state of T cells. The predominant influences of T cells in this respect are inhibitory cytokines that bind cell surface receptors and influence transcriptional changes that favor decreased activation. Two cytokines that serve as a paradigm for understanding cytokine-mediated inhibition of T cells are IL-10 and TGF-β.

Interleukin-10 is a major negative regulator of immune effector function. Its central role is underscored by the fact that pathogenic viruses, such as cytomegalovirus and Epstein-Barr virus, use homologs of IL-10 to subvert immunologic activity and create environments more favorable for viral spread and replication. IL-10 is produced by both innate and adaptive immune cells in response to activation. As with other cytokines, binding of IL-10 to the IL-10 receptor induces signaling through JAKs, resulting in the nuclear translocation of STAT proteins and the implementation of a transcriptional program that results in decreased expression of inflammatory cytokines and in antagonism of crucial signaling molecules.

Interleukin-10 exerts broad changes within the immune system. In monocytes, IL-10 decreases the production of inflammatory mediators and antigen presentation. In T cells, the effects of IL-10 are generally inhibitory, resulting in decreased capacity for proliferation and a decreased capacity to secrete cytokines. These effects vary by T-cell subtype, however, because IL-17 secretion by Th17 cells is not impaired in the presence of IL-10. As in other proteins important in the negative regulation of T cells, *il10* germline deletion often results in fatal autoimmunity, in this case a gastrointestinal disease resulting from the inability to control inflammation caused by commensal bacteria.

TGF-β is important for upregulating the transcription factor FoxP3 in Tregs. This cytokine also elicits more global changes that favor immunosuppression. TGF-β binds its cell surface receptor and subsequently induces the phosphorylation, activation and nuclear transport of the intracellular Smad proteins. Smad proteins exert their effects by directly coordinating transcriptional programs that inhibit immune responsiveness. Similar to IL-10, TGF-β acts on numerous cell types. It has been shown to inhibit the differentiation of effector Th cells; induce the conversion of naïve T cells into Tregs; suppress the proliferation and production of IL-2 by T cells; and inhibit the activity of macrophages, DCs, and APCs. Mice lacking TGFβ-1 develop autoimmune-mediated multiorgan failure and die shortly after birth, underscoring the important role that this molecule plays in attenuating immune reactions.

Terminating Immune Responses After Pathogen Clearance

The simplest way in which T-cell responses end after clearance of a pathogenic challenge is by the removal of antigen, which limits the perpetuation of T-cell activation and abrogates the recruitment of new effector cells. Effector functions of T cells that were stimulated to respond to the pathogen challenge also diminish as the inhibitory mechanisms already described exert their effects. However, homeostasis of the immune system also requires that the majority of the T cells that emerged from the clonal expansion of antigen stimulated cells (at its peak representing several percent of the hosts' T-cell

pool) be eliminated, retaining only the small population of memory T cells responsive to the inciting antigens. Elimination of the expanded population occurs through activation-induced cell death (AICD).

Activation-induced cell death is initiated when CD95 (also called Fas), a T-cell surface receptor present on the activated effector cells, is engaged by its ligand, CD95 ligand, expressed on multiple immune cells, including the activated cells themselves. CD95 is a member of the TNF family of receptors and, when stimulated, recruits the adapter molecule Fas-activating via death domain (FADD). FADD creates a multimolecular complex that triggers the activation of several intracellular caspases that induce DNA damage and apoptosis of the effector T cell. During T-cell activation, both CD95 and CD95 ligand are upregulated on the surface of the cell, and all of the machinery is present to initiate AICD. Hence, the default pathway for activated T cells is apoptosis, an event that is blocked when T cells are appropriately stimulated to respond to antigen. After antigen is cleared and the stimulatory events cease, AICD takes over, reducing the expanded population of cells (Fig. 19-11).

Experiments of nature have taught us much about the biology and importance of both CD95 and CD95 ligand. Loss of these proteins as well as components of their signaling machinery results in autoimmune lymphoproliferative syndrome (ALPS). ALPS is characterized by massive enlargement of lymphoid organs, autoimmune cytopenias, and an increased risk of hematologic malignancy.

THERAPEUTIC MANIPULATION OF T CELL–MEDIATED IMMUNITY

A comprehensive description of the myriad ways in which the manipulation of T cells has led to important clinical advances is beyond the scope of this chapter. However, it is worth appreciating some of the ways in which an enhanced understanding of T cell–mediated immunity has resulted in changes in clinical practice. Many human diseases are related to T-cell dysfunction, both in cases of overexuberant immune responses, as in autoimmune diseases and rejection of transplanted organs, and in insufficient immune responses, as in the case of some chronic infections and in uncontrolled malignancy. Here, we briefly address T-cell responses in graft rejection and in malignancy as paradigms for how T-cell immunity has been modulated therapeutically.

The success of solid organ transplantation depends greatly on the ability to control the immune response of the recipient against the donor organ. Donor tissues express foreign MHC alleles and other proteins to which endogenous T cells have not been exposed (and tolerized against) during thymic development, and thus these tissues serve as potential targets for T cell–mediated immunity. Initially, the only medications capable of permitting graft survival were high-dose steroids, medications with potent effects in essentially all organ systems and with severe side effects not limited to the immune system. Subsequently, however, several classes of medications were identified that act more specifically on T cells, first cyclosporine and subsequently tacrolimus and sirolimus. These medications target the IL-2 axis: cyclosporine and tacrolimus inhibit IL-2 transcription, and sirolimus inhibits mammalian target of rapamycin (mTOR), a group of proteins crucial in facilitating IL-2 signal transduction. Because T cells, depending on the treatment agent, are either unable to produce IL-2 or respond to IL-2, they fail to proliferate despite conditions favorable for stimulation, leading to impaired T cell–mediated immunity and improved survival of transplanted organs.

Other agents currently in use in the clinic were also designed precisely because of insights that emerged from studies probing the molecular basis of immune cell function. For example, antibodies directed against CD3 are potent T-cell inhibitors and are now used in the setting of acute solid organ transplant rejection. Similarly, blocking the IL-2 receptor with monoclonal antibodies prevents IL-2 receptor signaling and thus abrogates division of stimulated T cells, thereby quelling T cell–mediated immune destruction.

Given the importance of costimulation for T-cell activation and the success in interfering with CD28 signaling in various autoimmune disorders, recent studies have demonstrated efficacy in transplant with blockade of the CD28–CD80/CD86 interaction using soluble CTLA-4 as a competitive inhibitor of the interaction between CD28 and CD80/CD86. A soluble CTLA-4 fusion protein has recently been approved in the setting of transplant rejection. Additional studies are in progress to examine ways in which modulation of other costimulatory receptors, alone or in combination with soluble CTLA-4, may be used to preserve allografts. As our understanding of how different T-cell subsets are induced is becoming more precise, new therapeutics on the horizon are designed to redirect immune responses by changing the balance of the various effector subsets that emerge as the recipient responses to the transplanted organ. Additional agents directed against receptors and signaling molecules discovered to be key for T-cell activation are currently being tested for clinical efficacy and safety and likely will soon be available to block T-cell responses in the setting of solid organ transplant.

In contrast to the need to impede immune responses in organ transplant, in the setting of malignancy, the desire is to intervene to enhance T-cell activity. T cells face several hurdles in their response to spontaneous malignancy. First, they must recognize peptides and proteins that are unique to tumor tissue. These include oncogenic mutant proteins, fusion proteins that may have formed during the course of tumor development, or aberrantly expressed embryonic proteins that result from altered transcription often found in malignant tissue. Second, T cells must overcome the lack of costimulation provided by tumor cells. Because tumor cells originate from normal host tissue, they fail to generate the bacterial or viral products crucial for activating APCs. Third, T cells must overcome the generally immunosuppressive microenvironment within tumor tissue, which may include an abundance of TGF-β, Tregs, immunosuppressive macrophages, the induction of an anergic-like state, and persistent antigen-induced exhaustion.

One approach to enhance T cell–mediated responses to tumors also makes use of the biology of CTLA-4. In this case, however, instead of using soluble CTLA-4 as an agent to inhibit T-cell responses by interfering with costimulation, antibodies against CTLA-4 are being tested as a means to block the ability of CTLA-4 expressed on activated T cells to inhibit T-cell function. Preliminary studies have shown that CTLA-4 blocking antibodies may prolong T-cell activation in response to malignancy, and their use has resulted in long-term disease remission in a small percentage of patients with metastatic melanoma, an otherwise uniformly fatal disease. Whether CTLA-4 antibodies mediate their effect by inducing the expansion of newly activated tumor-specific cells or by reversing the immunosuppressive microenvironment on existing cells remains to be determined. In addition to targeting CTLA-4 to abrogate its ability to inhibit T-cell responses, preliminary approaches are underway to block other inhibitory receptors or ligands to enhance T-cell immunity. One promising example is targeting of PD-1, the inhibitory receptor present on activated and exhausted T cells, with the hope of boosting T-cell responses against cancers and promoting clearance of pathogenic viruses that now typically persist in the host.

In addition to targeting inhibitory receptors on T cells to augment antitumor responses, studies are underway to engineer APCs to more effectively stimulate effector T-cell responses (e.g., through enhanced expression of ligands for activating costimulatory receptors). Such APCs are being tested in clinical trials for effectiveness as tumor vaccines. Investigators are making use of our understanding of the most proximal events important for T-cell activation to develop chimeric antigen receptors (CARs). These engineered molecules include a binding site for an antigen thought to be expressed selectively (or relatively so) by tumor cells coupled to the transmembrane and cytoplasmic signaling components of the ζ chain of the TCR complex and other key activating receptors. T cells are removed from patients and then transfected with cDNA encoding these "engineered" receptors ex vivo. The modified T cells are then administered back into the patients with the anticipation that these T cells will engage the tumor through the CAR, which will also transduce a signal to activate the T

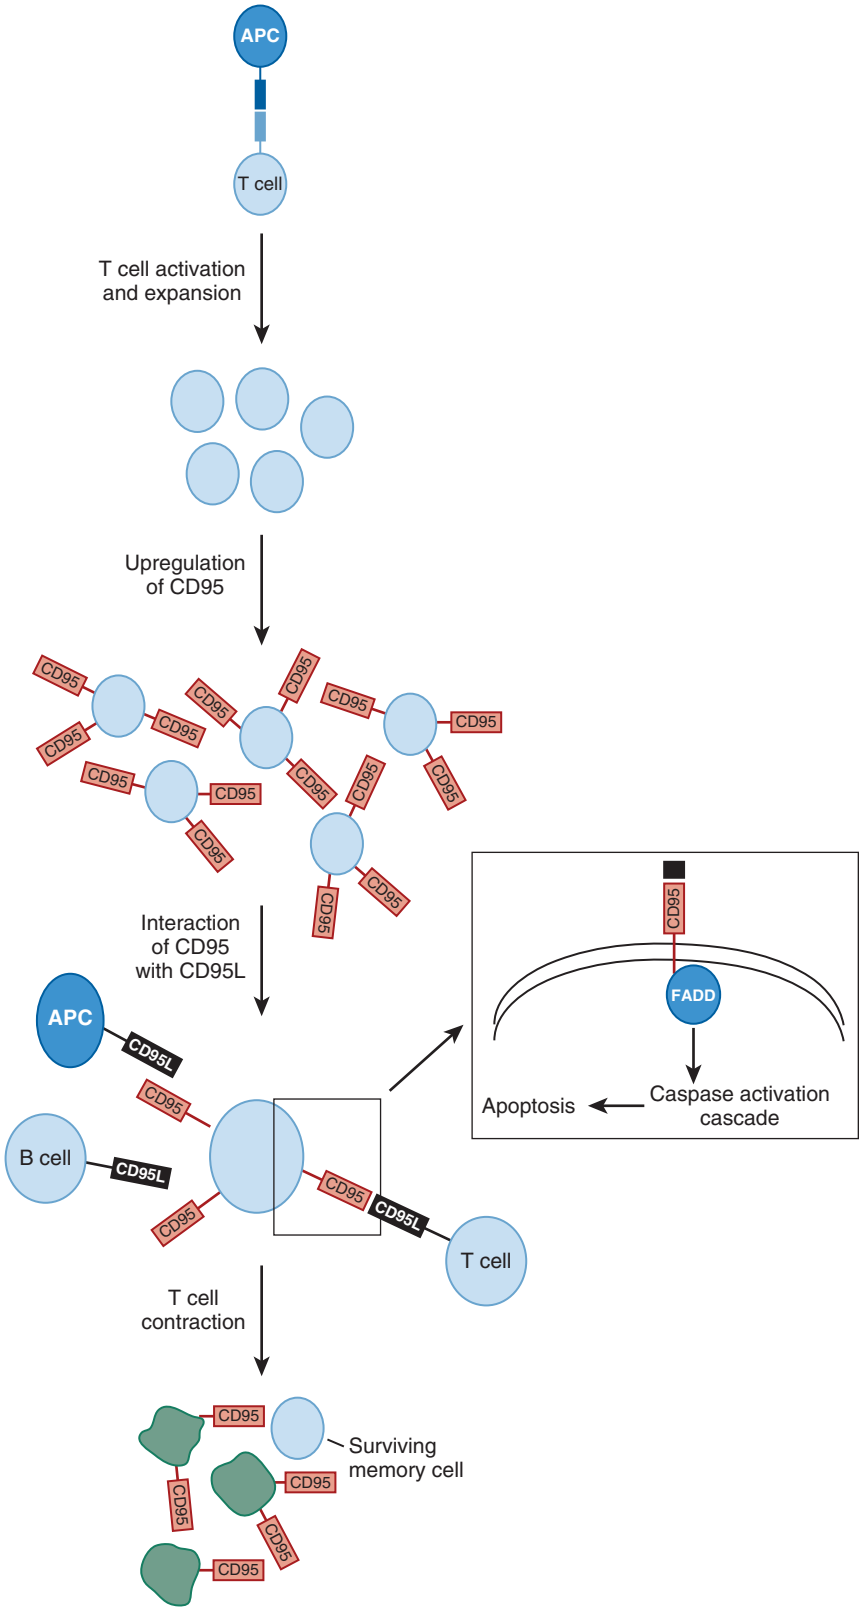

Figure 19-11 CD95-DEPENDENT ACTIVATION-INDUCED CELL DEATH. After T-cell activation and resultant expansion, T cells begin to upregulate the cell death receptor CD95. The ligand for CD95, CD95L, is expressed on many cell types, including APCs, B cells, and the activated T cells themselves. Binding of CD95 to CD95L triggers recruitment of the adapter protein Fas-activating via death domain (FADD), resulting in activation of caspases and the induction of cell death through apoptosis. The process of CD95 upregulation and apoptosis leads to contraction of activated T-cell populations.

cell. These activated T cells with reactivity against the tumor are designed to mount a robust antitumor response, bolstering antitumor immunity sufficiently to eliminate the cancer. Although studies using such agents are only beginning, early results are promising.

The examples presented here are only a small subset of novel approaches in use or being tested to modulate immune cell function based on our understanding of the molecular basis of T-cell activation. It is anticipated that as more is learned about the molecules and pathways critical for control of T cell–mediated immunity, additional new agents with greater efficacy and improved safety profiles will become available for clinical use. The advent of these new therapeutics and their potential to improve treatments for serious human diseases underscore the importance of continued efforts to understand the mechanisms of T-cell development and function.

CHAPTER 20

NATURAL KILLER CELL IMMUNITY

Don M. Benson, Jr., and Michael A. Caligiuri

Natural killer (NK) cells are large granular lymphocytes comprising about 10% to 15% of the peripheral circulation.[1,2] First characterized by their ability to lyse targets independent of activating or initiating stimuli,[3] NK cells are a critical cellular component of the innate immune system. In addition, NK cells secrete cytokines that help to marshal and shape the innate and adaptive immune response to infection and malignant transformation. There has been a recent surge of interest in NK cells as new discoveries in both the laboratory and the clinic have characterized the crucial contributions of NK cells in shaping the early immune response.[4] NK cells play a key role in maintaining host defense as exemplified in human NK cell deficiency syndromes (which carry increased susceptibility to overwhelming viral, intracellular, and atypical mycobacterial infections),[5] and animal models of NK cell deficiency (e.g., such mice are particularly susceptible to developing cancer).[6,7] This chapter reviews current understanding of NK cell biology, the role of NK cells in human diseases, and the recent clinical applications of NK cells in cancer therapy.

FUNDAMENTAL BIOLOGY

Natural Killer Subsets

Natural killer cells are phenotypically recognized by surface expression of CD56 (also called neural cell adhesion molecule [NCAM]) and the absence of the T-cell–specific surface antigen CD3 as well as the T-cell receptor(TCR).[8,9] Based on the intensity of CD56 surface expression, two functional subsets (so-called $CD56^{bright}$ and $CD56^{dim}$) of NK cells may be discriminated from one another. $CD56^{dim}$ NK cells comprise 85% to 90% of the NK cells in peripheral circulation and are potent mediators of cytotoxicity. About 10% to 15% of NK cells in the circulation are $CD56^{bright}$, and upon activation, this subset is capable of robust cytokine and chemokine production.[2] Fig. 20-1 graphically represents the NK subsets described below, and Table 20-1 summarizes major surface antigens associated with each NK cell subset.

$CD56^{dim}$ Natural Killer Cells

$CD56^{dim}$ NK have exquisite cytolytic properties, able to kill infected as well as tumor cell targets without prior sensitization.[10] They constitutively express the interleukin-2/15 (IL-2/15) receptor (R) β and common γ-receptor chains, which together form a receptor complex through which cells may respond to stimulation by either IL-2 or IL-15.[11,12] $CD56^{dim}$ NK cells can lyse tumor cell targets through at least three distinct mechanisms. First, they can execute cytotoxicity through granule exocytosis of perforin and granzyme.[13,14] Second, cytotoxicity can be mediated through FasL and TRAIL associated with production of cytokines, including interferon-γ (IFN-γ), tumor necrosis factor α (TNF-α), and granulocyte macrophage colony-stimulating factor (GM-CSF).[15] Third, $CD56^{dim}$ NK cells can mediate antibody-dependent cytotoxicity (ADCC) via the high-density surface expression of CD16 (the FcγRIII receptor).[2,16] Freshly isolated, unstimulated $CD56^{dim}$ NK cells have intrinsically greater cytotoxicity against NK-sensitive targets such as the K562 cell line in vitro compared with the $CD56^{bright}$ NK cells.[17]

Other antigens are differentially expressed by $CD56^{dim}$ NK cells and provide insight into their functional role in the immune response. For example, $CD56^{dim}$ NK cells also exhibit relatively high surface density expression of killer immunoglobulin-like receptors (KIRs). NK cell KIR expression appears important in preventing autoimmunity and in surveying against malignant transformation.[16,18]

Both $CD56^{dim}$ and $CD56^{bright}$ NK cells express modest levels of the chemokine receptor CXCR3. However, in contrast to $CD56^{bright}$ NK cells, $CD56^{dim}$ NK cells display relatively abundant surface expression levels of CXCR1, CXCR4, and CX3CR1.[19] CXCR1 binds IL-8, and CXCR4 binds SDF-1 (stromal cell-derived factor). These cytokines are associated with local inflammatory response; for example, IL-8 levels are increased in the setting of acute viral infections,[20] and IL-8 and SDF-1 levels are increased with solid[21,22] and hematopoietic malignancies.[23,24] Thus, expression of these chemokine receptors allows NK cells to traffic to local areas of inflammatory response to mediate antiviral and antitumor activity.

$CD56^{bright}$ Natural Killer Cells

$CD56^{bright}$ NK cells play more of an immunoregulatory role. $CD56^{bright}$ NK produce a multitude of cytokines and chemokines, have a relatively high proliferative capacity, reside primarily in the parafollicular T cell–rich region of secondary lymphoid tissue (SLT), and have modest cytolytic granules, KIR, and FcγRIII expression (see Table 20-1).[10] $CD56^{bright}$ NK cells are unique among cytotoxic effector cells in constitutive expression of the high-affinity IL–2Rαβγ complex, making them responsive to picomolar concentrations of IL-2 released by activated T cells in the parafollicular T cell–rich region of SLT.[25] As noted, $CD56^{bright}$ NK cells comprise only about 10% of the circulating NK population but predominate almost to the exclusion of the $CD56^{dim}$ NK subset in SLT.[2,26] This likely results from their selective expression of a number of receptors that assist in homing cells to and retaining cells in SLT (e.g., CCR7 and CD62L).[10]

The ability of $CD56^{bright}$ NK cells to produce an abundant variety of cytokines and chemokines compared with the $CD56^{dim}$ subset likely relates more to the differential expression of both negative and positive regulators of cytokine/chemokine production and less to constitutive expression of cytokine-activating receptors. For example, $CD56^{bright}$ NK cells have little or no expression of two negative regulators of cytokine/chemokine production, namely SHIP-1 (Src homology-2 domain-containing inositol 5-phosphatase 1) and HLX (H2.0-like homeobox 1),[27,28] but $CD56^{dim}$ NK lack constitutive expression of a positive regulator of cytokines called SET.[29]

NATURAL KILLER CELL DEVELOPMENT

Interleukin-15 is required for NK cell development in mouse and humans,[30,31] and as with B cells and T cells, human NK cells are derived from $CD34^{(+)}$ hematopoietic stem cells in bone marrow (BM). However, NK cell precursors in human BM have not been

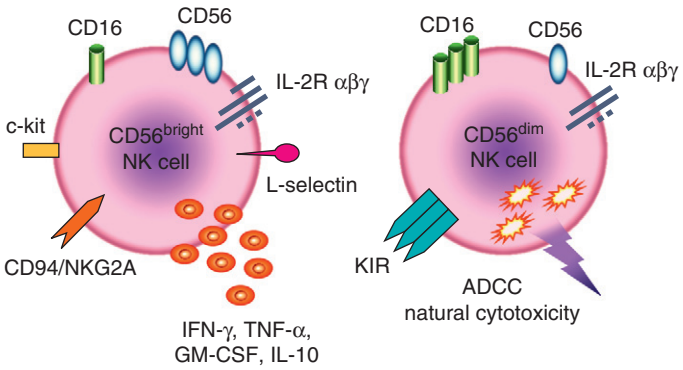

Figure 20-1 SIMPLIFIED REPRESENTATION OF NATURAL KILLER CELL SUBSETS. $CD56^{bright}$ cells have immunoregulatory function whereas $CD56^{dim}$ cells have cytolytic function. *ADCC,* Antibody-dependent cellular cytotoxicity; *GM-CSF,* granulocyte macrophage-colony stimulating factor; *IFN,* interferon; *IL,* interleukin; *KIR,* killer immunoglobulin-like receptor; *R,* receptor; *TNF,* tumor necrosis factor. *(Adapted from Cooper MA, Fehniger TA, Caligiuri MA: The biology of human natural killer cell subsets.* Trends Immunol *22:633, 2001.)*

Table 20-1 Human Natural Killer Cell Subsets Display Different Repertoires of Surface Antigens

Antigen	$CD56^{dim}$	$CD56^{bright}$
CD16 (FcγRIIIa)	+++	–/+
KIR	+++	–/+
CXCR1	+	–
CXCR3	++	–
CX3CR3	+	–
CXCR4	++	–
CD94	–	++
NKG2A	–/+	+
NKG2D	+	+
c-kit	–	+
CCR7	–	++
CD2	++	+++
CD62L (L-selectin)	+	++
CD44	+	++

KIR, Killer immunoglobulin-like receptor.

identified, suggesting that maturation may occur elsewhere.[2,32] Freud et al identified a $CD34^{dim}CD45RA^{(+)}\alpha4\beta7^{bright}$ cell to be the only $CD34^{(+)}$ subset in SLT.[26] Found within the parafollicular T cell–rich region of SLT in the same region as the $CD56^{bright}$ NK cell, this $CD34^{dim}CD45RA^{(+)}\alpha4\beta7^{bright}$ cell can differentiate into a $CD56^{bright}$ NK cell in the presence of IL-15.[22] With evidence for a $CD34^{(+)}$ NK precursor and $CD56^{bright}$ NK cell in the same region within SLT, five novel, discrete stages of NK cell development were characterized in situ within the same parafollicular region of SLT, each by their differential expression of CD34, CD117, and CD94.[33,34] As development proceeds along this continuum, cells acquire the ability to secrete cytokines (e.g., INF-γ); display natural cytotoxicity; and lose the ability to differentiate into dendritic cells (DCs), T cells, or both. This orderly development in SLT from a $CD34^{(+)}$ subset to $CD56^{bright}$ NK cells suggests that $CD56^{dim}$ NK cells represent a terminally differentiated NK stage that follows $CD56^{bright}$ NK development and exit into the periphery. Interestingly, the expression of CD94 may mark

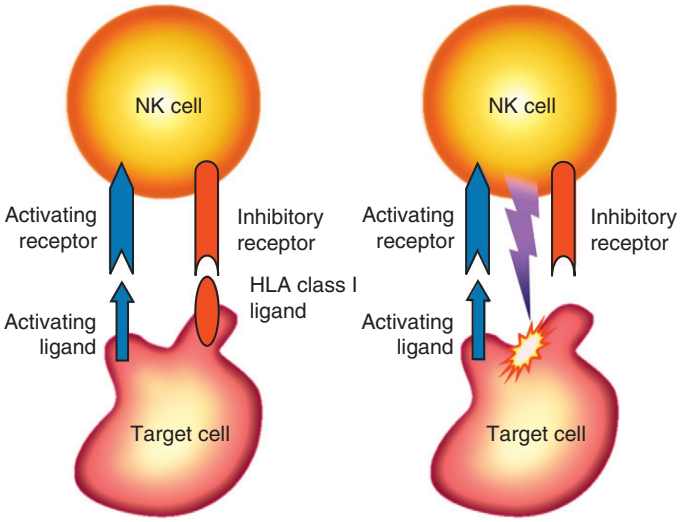

Figure 20-2 SIMPLIFIED REPRESENTATION OF NATURAL KILLER (NK) CELL CYTOTOXICITY MEDIATED THROUGH THE BALANCE OF ACTIVATING AND INHIBITORY SIGNALING IN RESPONSE TO LIGANDS ON POTENTIAL TARGETS. The target cell on the left is spared, but the target cell on the right is lysed. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect.* Blood *100:1935, 2002.)*

a functional intermediary step between $C56^{bright}$ and $CD56^{dim}$ human NK cells.[35] The abundance of $CD56^{dim}$ NK cells in blood versus SLT and their loss of both CD117 (c-kit) expression and proliferative capacity along with their acquisition of KIR, FcRγRIII, and cytolytic granules are all consistent with this notion.[2] More recently, CD57 has been identified as a surface marker of terminally differentiated NK cells.[36]

NATURAL KILLER CELL RECEPTORS

Natural killer cells, as opposed to B and T lymphocytes, do not undergo clonotypic gene rearrangement in order to express antigen receptors; however, through the expression of a complex repertoire of surface molecules, NK cells may efficiently determine nonself from self and rapidly initiate an appropriate response.[37] NK cell receptors may be activating or inhibitory—in other words, binding of the receptor to its ligand expressed on a target cell either activates or suppresses a functional NK response. Such receptors fall into three general categories: those which are members of the immunoglobulin-like superfamily (KIR), one type that belongs to the C-type lectin receptor (CLR) superfamily,[38] and finally NK cell–specific receptors (NKRs). The complex function of these receptor subsets is still a matter of intense research; however, a model by which NK cell receptors KIR may recognize particular features of major histocompatibility complex (MHC) class I alleles (e.g., human leukocyte antigen A [HLA-A],[39] HLA-B,[40] HLA-C[41]) or recognize other surface antigens on target cells has been developed.[42,43] Fig. 20-2 is a simplified, schematic representation of what we currently understand regarding the ability of NK cells and their receptors to survey the immune system.

Killer Immunoglobulin-Like Receptors

KIRs provide one method by which NK cells recognize self from nonself to mediate the appropriate cytotoxic response. There are at least 15 KIRs identified on chromosome 19q13.4.[18,42,43] Structurally, KIRs contain two or three extracellular immunoglobulinlike domains and recognize MHC class I proteins.[18,39,40] KIRs may be either inhibitory or activating, a functional feature associated with

the intracellular tyrosine-based motif of the molecule.[18] All of this information may be deduced for a particular receptor through the nomenclature used to identify KIRs. The number of Ig-like domains (two or three) is expressed (e.g., KIR2D or KIR3D), and the length of the intracytoplasmic tail (i.e., a long [L] inhibitory tail or a short [S] activating tail) is also incorporated (e.g., KIR2DL or KIR2DS). A suffix numeral follows the identification of some KIR to represent polymorphic forms of each receptor (e.g., KIR2DS2 and KIR2DS3, each indicating a polymorphic form of an activating KIR that bears the same extracellular domains). HLA-C is particularly important in KIR-mediated self/nonself recognition because many well-described KIR have ligand specificity for HLA-C associated antigens. For example, the inhibitory receptor KIR2DL1 (CD158a) recognizes group 2 HLA-C Asn77Lys80 (HLA-Cw2, w4, w5, w6 and related alleles), and the inhibitory receptors KIR2DL2 and KIR2DL3 recognize group 1 HLA-C Ser77Asn80 (HLA-Cw1, w3, w7, w8 and related alleles).[43] Activating receptors KIR2DS1 and KIR2DS2 recognize the same group 2 and group 1 antigens as the inhibitory counterparts; however, generally, inhibitory receptors bind with greater avidity or attraction for a corresponding HLA antigen than activating receptors.[44] Complementary activating and inhibitory KIRs recognize the same cognate extracellular domains on target cells; thus if an NK cell expresses both activating and inhibitory KIR for an identical ligand, the cell will generally be inhibited from killing.

The KIR family is likely not all inclusive for human classical type I HLA allotypes; for instance, only one inhibitory KIR directed against HLA-A (KIR3KL2) and none toward HLA-B alleles have been found.[43] Additionally, specific KIRs may have particular roles in maintaining host immunity in unique settings. For example, KIR2DL4 recognizes the nonclassical HLA-G molecule that is only expressed on fetal extravillous trophoblasts that invade the maternal decidua during pregnancy.[45] Controversy surrounds the exact nature of this KIR; however, KIR2DL4 is likely not clonally distributed as other KIRs but is present on the surfaces of most mature NK cells.[46] Interestingly, despite having an inhibitory intracellular signaling moiety, KIR2DL4 serves to promote IFN-γ secretion but not cytolytic activity.[46] It is possible that this KIR functions to facilitate immune tolerance to developing fetuses.[47]

C-Type Lectin Receptors

C-type lectin receptors (CTLRs), located on human chromosome 12p.12.3, share a common subunit (CD94) covalently bonded to one of four closely related gene products of the NKG2 family.[48,49] CTLR represent a second type of NK cell receptor–mediating killing and include NKG2A (and splice variant B), NKG2C, NKG2E (and splice variant H), and NKG2F.[49] NKG2D, which does not bind CD94 and shares little sequence homology to other NKG2 proteins, is discussed later. All but one of the CTLRs are activating and expressed on NK cells and cytotoxic T lymphocytes. CD94/NKG2A is inhibitory and is expressed on NK cells as well as cytotoxic T lymphocytes where they serve to regulate CD8(+) T-cell antiviral responses.[50] CD94/NKG2A specifically recognizes the nonclassical HLA-E Class I molecule.[51] Interestingly, HLA-E specifically presents leader peptides from other HLA receptor antigens; thus, sensitivity to HLA-E provides a mechanism for NK cells to sense functional overexpression of class I MHC molecules on cell surfaces. As with KIR, binding between CD94/NKG2A and HLA-E is more avid than binding of activating CTLRs to other epitopes, however, unlike KIR, the target antigens for activating and inhibitory CTLR are not the same.[52]

NKG2D is a CTLR, however, it has only modest sequence homology with other members of the NKG2 family and does not associate with CD94.[51] NKG2D exists as a homodimer and does not have inherent signaling capability but rather signals via the PI3K pathway as recruited through DAP10Wu or KAP10.[53] This unique signal transduction arrangement renders NKG2D signaling privileged from inhibitory, intracellular intermediaries that modulate signal transduction of other CTLR systems. NKG2D is constitutively expressed on all NK cells, γδ T cells, and CD8(+) T cells.[54]

NKG2D mediates killing of cellular targets expressing two antigens associated with viral or neoplastic transformation.[43,55] First, MHC class I chain-related antigens (MICs) are a family of proteins whose expression correlates with heat shock and viral and neoplastic transformation.[54,56] MICA and MICB expression are under control of promoter elements similar to that of heat shock proteins and have been shown to be upregulated in the setting of cytomegalovirus (CMV) infection as well as in a number of epithelial and hematologic malignancies.[56,57] Second, UL16 binding protein (ULBP) serves as a ligand for NKG2D. UL16 is a type I transmembrane protein ubiquitously expressed in the setting of CMV infection.[58] UL16 binds MICB and two other proteins, ULBP-1 and ULBP-2.[59] (These latter proteins have α1 and α2 domains but lack an α3 domain as MIC and MHC class I molecules have; furthermore, they are expressed via a glycosylphosphatidyl inositol [GPI] anchor and thus have no requirement for β2 microglobulin.) In binding MICB, ULBP-1, and ULBP-2, CMV-produced UL16 counteracts cell surface expression of these NKG2D ligands, thus providing a mechanism of immune evasion from NK cell surveillance and cytotoxicity.[60] In a similar fashion, some human tumors downregulate expression of NKG2D ligands or release soluble forms of such (e.g., MICA or ULBPs) as a mechanism of immune escape from NK cells.[61-63] Although ULBPs are expressed more ubiquitously than MIC proteins, some tissues with high mRNA levels express no protein, implying important post-transcriptional control of these antigens.[59] IL-15 stimulation enhances the NK cell NKG2D-mediated response to tumors expressing ULBP.[64]

Other Activating Natural Killer Receptors

A third family of NK receptors that mediate cell killing are called natural cytotoxicity receptors (NCRs).[57,65] In addition to NKG2D, NCRs comprise an important family of activating NK cell receptors involved in the process of target recognition and elimination. NCRs include three receptors called NKp46 and NKp30, which are exclusively and constitutively expressed on NK cells, and NKp44, which is expressed after IL-2 stimulation on NK and some γδ T cells.[57,65,66] Infectious, pathogen-specific ligands for NCR have been identified (e.g., NKp46 and NKp44) that recognize and engage virus specific hemagglutinin and hemagglutinin-neuraminidase.[67] This provides a mechanistic understanding of how NK cells can target and eliminate cells infected with influenza and parainfluenza virus (e.g., although such target cells have not downregulated MHC class I expression).[67] Recently, B7-H6 has been identified as a ligand for NKp30; however, endogenous ligands for other NCR remain to be identified.[68-70]

ADAPTIVE IMMUNE PROPERTIES OF NATURAL KILLER CELLS

Recent findings regarding NK cell biology have blurred the functional borders between the innate and adaptive arms of the immune system. Although NK cells have traditionally been dichotomized into the innate immune system, emerging data suggest that NK cells demonstrate sophisticated adaptive properties and do not interact in an invariant manner in the microenvironment.[71]

Natural Killer Cell Education

The potential for NK cell autoreactivity exists because some NK cells may lack inhibitory receptors, but others may express activating receptors for self ligands. This can occur because the receptor array that individual NK cells express occurs largely at random and ligands to these receptors are inherited independently.[72] Potentially autoreactive NK cells are not clonally deleted but rather rendered hyporesponsive. For example, NK cells lacking inhibitory receptors for self MHC are unresponsive to self cells.[73] And in a complementary manner, humans who lack MHC class I expression do not experience NK cell–mediated autoimmunity. By comparison, through an

MHC-dependent processing termed *licensing,* NK cells that express receptors for self MHC exhibit greater responsiveness to stimulation; however, their effector function against normal cells is blocked by engagement of inhibitory receptors for self MHC.[74] Whether responsiveness is determined by interaction with cells expressing ligands for NK cell receptors (so-called "arming") or hyporesponsiveness is induced via encounters with normal cells lacking MHC ligands ("disarming" or "anergy") is unclear; however, experimental data suggest that persistent stimulation results in hyporesponsiveness but persistent stimulation with concomitant inhibition leads to NK cell responsiveness.[75,76] Studies such as these and others suggest that NK cells may be sensitive to changes in the microenvironment and may modulate responsiveness to stimuli.

Natural Killer Cell Memory

Immunologic memory has long been reserved as a process of the adaptive immune system; however, recent data suggest that NK cells possess a form of memory as well. This idea was first demonstrated in a recombinase-activating genes-1 (RAG-1) deficient mouse lacking T and B cells. Hapten-induced hypersensitivity was mediated by NK cells in this model, and "memory" NK cells were described as residing in the liver and bearing Thy1 and CXCR6 on their surfaces.[77]

This concept has also been demonstrated in the setting of viral infection in mice with vesicular stomatitis virus, HIV-1, influenza, and murine CMV (MCMV).[77,78] In regards to MCMV, for instance, Ly49H(+) NK cells recognize MCMV m157 glycoprotein, resulting in NK-cell mediated control of the disease. These Ly49H$^+$ NK cells preferentially expand in the setting of infection and contract after infection is controlled. However, "memory" NK cells could be detected months after infection, and upon restimulation, these NK cells exhibited augmented cytotoxicity and cytokine production against MCMV.[78] Although a unique marker of memory is unclear, these NK cells stably express KLRG1, a cadherin-recognizing inhibitory receptor, and could be detected 2 months after infection control even in adoptive transfer models.[78]

THE ROLE OF NATURAL KILLER CELLS IN HUMAN DISEASE

Natural killer cell deficiencies are rare; however, such conditions provide insight into the role NK cells play in response to infectious pathogens, autoimmune disorders, and the development of malignancy. Selective NK cell deficiency has not been associated with a particular Mendelian disorder[79]; however, studies have shed new light on the genetic mechanisms responsible for proper NK development and function. Many syndromes have been linked to increased susceptibility to infection, and others may predispose to autoimmune disease.

Natural Killer Deficiency Syndromes Linked to Increased Infectious Risks

The first gene directly implicated in NK deficiency was FCGR3A, which codes for FcγRIIIa (CD16) expressed on NK cells. A "T ◇ A" substitution at position 230 leads to coding of a lysine residue at position 48, normally a histidine. Although the protein expressed appears phenotypically normal, patients present with increased susceptibility to severe and disseminated herpes simplex virus (HSV) infections.[80] Other patients present with progressive Epstein-Barr virus and varicella infections.[81] Patients have variable deficits in NK cytotoxicity and responsiveness to cytokine stimulation. Population studies have subsequently suggested that the H48 allele may be necessary but not sufficient to produce clinical disease.[82]

Clinical examples of patients entirely lacking any CD56$^+$ lymphocyte subsets have been reported. The first report was a young patient who presented with life-threatening varicella infection. She subsequently developed CMV pneumonia and cutaneous HSV infection. Analysis of her lymphocyte subsets demonstrated a striking and selective absolute absence of CD56$^+$ or CD16$^+$ cells.[5] The patient went on to develop aplastic anemia and expired from complications of stem cell transplantation.[82] A second patient presented with disseminated *Mycobacterium avium* went on to die of disseminated varicella.[83] Other patients have been described with an isolated deficiency of CD56$^+$/CD3$^-$ lymphocytes but with normal or even increased populations of CD56$^+$/CD3$^+$ cells. One such patient presented with severe, recurrent human papilloma virus–related condylomatous disease.[84] Although the genetic mechanisms of these diseases remain unknown, they highlight the functional role of NK cells in providing immunity toward infectious pathogens.

Natural killer cell deficiencies have been described as a component of other disease processes affecting multiple hematopoietic and immune lineages. The genetic deficiencies responsible for many of these disorders have been described and can be found in Table 20-2.

The Role of Natural Killer Cells in Autoimmunity

Interestingly, NK cells have been implicated in both the regulation and pathogenesis of autoimmune disorders. For example, in a murine experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis in which disease is induced with myelin oligodendrocyte glycoprotein (MOG), NK depletion leads to enhanced T-cell response to MOG. Similarly, in human multiple sclerosis, NK cells have been implicated in the maintenance of disease remission.[85] NK cells have also been shown to control inflammation in an experimental model of autoimmune colitis.[86] NK cells may exert this effect through recognition and elimination of T cells activated against autoantigens.[87]

There are also examples of NK cells promoting autoimmune disorders. For instance, experimental evidence supports the idea that NK cells may promote development of type 1 diabetes mellitus through targeted elimination of pancreatic islet β cells after viral infection.[88] Other studies suggest that NK cells can promote humorally mediated autoimmune diseases such as myasthenia gravis through potentiation of autoreactive B cells.[89] Synoviocytes of patients with rheumatoid arthritis (RA) have been shown to express abnormally high levels of MICA, the previously described ligand for NKG2D.[90,91] In fact, NK cells present in acute RA joint effusions may perpetuate this autoimmune inflammatory response.[92]

Finally, NK cell receptor polymorphisms have been implicated in the pathogenesis and progression of autoimmune disease. For example, a T ◇ G substitution at position 559 in the FcγRIIIA (CD16) gene leads to a phenylalanine to valine substitution at residue 176 of the FcγRIIIA protein.[93] Although the receptors are expressed similarly on the cell membrane, the V/V homozygous state is associated with a higher affinity for IgG binding than the F/F state. The low binding state (F/F) is associated with lupus nephritis.[94] Others have confirmed this observation by genetic linkage studies in patients with systemic lupus erythematosis.[95] Another polymorphism in the FcγRIIIA receptor (158V/F) has been associated with RA in certain ethnic groups.[96] This mutation may also be associated with development of subcutaneous rheumatoid nodules in patients with established RA.[96] As CD16 expressed on a number of immune cells, the specific role of NK cells contributing to pathology is unclear; however, as discussed later, these polymorphisms have also been linked to response to enhanced response to monoclonal antibody therapy of cancer.

THE THERAPEUTIC POTENTIAL OF NATURAL KILLER CELLS

T lymphocytes depend on recognition of tumor-specific antigens to effect antitumor immune response, an approach limited by our inability to identify such targets for the vast majority of nonviral neoplasms. NK cells, on the other hand, have long been recognized

Table 20-2 Human Disorders Characterized in Part by Natural Killer Cell Deficiency

Disease	Gene	Protein	Cell Count	Cytotoxicity	ADCC	Cytokine Response
X-linked SCID	*1.1.1.1.1.1.1.1 IL2Rg*	Common g chain	Low/absent	Low/absent	N/A	Reduced
Autosomal recessive severe combined immunodeficiency	*1.1.1.1.1.1.1.2 JAK3*	Janus kinase 3	Low/absent	Low/absent	N/A	N/A
Bloom syndrome	*1.1.1.1.1.1.1.3 BLM*	Bloom helicase	Normal	Low	N/A	Normal
Chediak-Higashi syndrome	*1.1.1.1.1.1.1.4 LYST*	Lysosome trafficking regulator	Normal	Absent	Absent	Reduced
Xeroderma pigmentosum	*1.1.1.1.1.1.1.5 XPAG*	DNA repair enzymes	Normal	Low	N/A	Normal
Familial erythrophagocytic lymphohistiocytosis	*1.1.1.1.1.1.1.6 PFP1*	Perforin	Normal	Absent	Absent	Reduced/absent
X-linked lymphoproliferative syndrome	*1.1.1.1.1.1.1.7 SH2-DIA*	SLAM-associated protein	Normal	Absent	Normal	Normal
Paroxysmal nocturnal hemoglobinuria	*1.1.1.1.1.1.1.8 PIG-A*	Phosphatidylinositol glycan class A	Low	Absent	Normal	Reduced/absent
von Hippel-Lindau syndrome	*1.1.1.1.1.1.1.9 NKTR*	Tumor recognition molecule	Normal	Absent	Normal	Reduced
Wiskott-Aldrich syndrome	*1.1.1.1.1.1.1.10 WASP*	WAS protein	High	Low	Low/normal	N/A
X-linked agammaglobulinemia	*1.1.1.1.1.1.1.11 BTK*	Bruton tyrosine kinase	Normal	Low	Low	N/A
Ectodermal dysplasia with immunodeficiency	*1.1.1.1.1.1.1.12 IKBKG*	NEMO	Normal	Low	Low/normal	Reduced
Common variable immunodeficiency	*TACI*	TNF receptor family member	Low	Low/normal	Low/normal	Normal

as being capable of antitumor rejection independent of such tumor antigens. As the understanding of how NK cells identify and eliminate targets has advanced, novel roles for the application of NK in clinical anticancer therapy have been defined. Three general approaches have been developed.

First, direct infusion of NK cells into patients with therapeutic intent has been performed.[97] This strategy has developed based on observations such as that in the allogeneic peripheral blood stem cell transplant (PBSCT) setting, where higher doses of transplanted NK cells have been associated with better outcomes as evidenced by reductions in posttransplant infections as well as reduction in nonrelapse mortality.[98] Several studies have shown this approach to be safe and associated with at least a modicum of effectiveness in the autologous setting.[99,100] At least one trial evaluating direct NK cell infusion has been reported in the allogeneic setting, correlating successful transfer and expansion of haploidentical NK cells with hematologic remission of leukemia.[101]

Second, NK cells have been successfully expanded in vivo in patients with cancer through the exogenous administration of recombinant human cytokines, such as low-, intermediate-, or high-dose IL-2.[102-106] The tumor nonspecificity of these strategies is being explored by concomitantly administering a tumor-specific monoclonal antibody whose Fc portion can bind to CD16 expressed on the cytokine-expanded NK cells, thus initiating a process called *antibody-dependent cellular cytotoxicity*.[105,107,108]

A third methodology under development to enhance the antitumor response of NK cells is based on the emerging understanding of KIR biology.[109] More than 20 years ago, an inverse relationship was reported between expression of MHC class I molecules on target cells and the ability of NK cells to kill such targets successfully.[37] As this "missing self" model was further characterized, three principal, common HLA class I allele specificities were identified that serve as ligands for three specific NK cell inhibitory KIR receptors. These have been termed "group 1" HLA-C alleles expressing Asn80 (e.g., HLA-Cw1, w3, w7, w8, and related alleles), "group 2" HLA-C alleles expressing Lys80 (e.g., HLA-Cw2, w4, w5, w6, and related alleles), and HLA-Bw4 alleles (e.g., HLA-B27). As one's NK receptor repertoire, including inhibitory KIRs, is dictated during development by the HLA class I genotype, ultimately every NK cell expresses at least one inhibitory KIR specific to self HLA class I molecules.[18] Moreover, allogeneic targets sensitive to NK cytotoxicity are identified by their lack of self MHC class I inhibitory KIR ligands.

These principles have been applied in a number of therapeutic settings. Perhaps most dramatically, Aversa and colleagues[110] have demonstrated an impressive improvement in survival after allogeneic stem cell transplantation–based therapy for patients with acute myeloid leukemia. Donor-versus-recipient NK cell alloreactivity has been shown to contribute to enhanced survival in this setting, as well as improved engraftment, and protection against graft-versus-host-disease.[111,112] In a series of patients receiving haploidentical grafts, 68% of patients without NK alloreactivity had relapsed disease, but only 15% of patients with NK alloreactivity relapsed with a median follow-up of 4 years.[111] Similarly, KIR-mismatch has been shown to improve outcome after reduced-intensity chemotherapy followed by allogeneic stem cell transplantation in multiple myeloma patients.[102,113] Fig. 20-3 shows how mismatching KIR epitopes facilitates NK-mediated tumor cytotoxicity in a haploidentical setting.

Others have extended on these transplantation-based findings by manipulating the relationship between NK receptors and MHC class I receptors through the means of monoclonal antibodies. For example, a murine model lends support to the notion that tumor expression of MHC class I molecules become engaged by inhibitory NK cell receptors and thus mediate NK tolerance.[114] When antibody fragments were introduced to disrupt this ligand–receptor interaction, increased NK cytotoxicity and decreased tumor growth were observed. Furthermore, adoptive transfer of murine NK cells pretreated with an antibody to block inhibitory NK receptor expression into leukemia-bearing mice led to enhanced survival as compared with transfer of untreated NK cells. These findings support the notion that blocking inhibitory NK receptors may be beneficial in increasing the

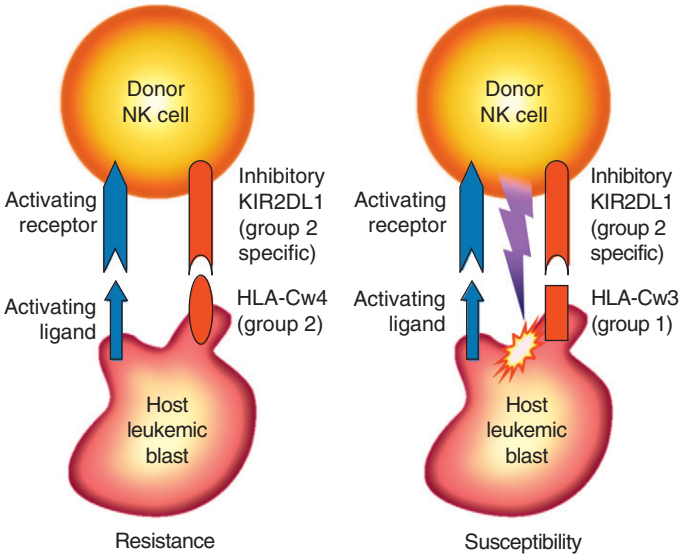

Figure 20-3 SIMPLIFIED REPRESENTATION OF HAPLOTYPE MISMATCHED ALLOGENEIC STEM CELL TRANSPLANT FOR ACUTE MYELOID LEUKEMIA: PROPER MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) CLASS I MISMATCH CAN LEAD TO DONOR NATURAL KILLER (NK) CELL KILLING HOST LEUKEMIC BLASTS. As the human leukocyte antigen C (HLA-C) ligand binds to the NK cell inhibitory killer immunoglobulin-like receptor (KIR) on the left, the inhibitory signal interrupts the activation signal, and no killing occurs. However, when the HLA-C ligand does not bind the NK inhibitor KIR on the right, no inhibitory signal is sent, and tumor killing occurs. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect.* Blood *100:1935, 2002.)*

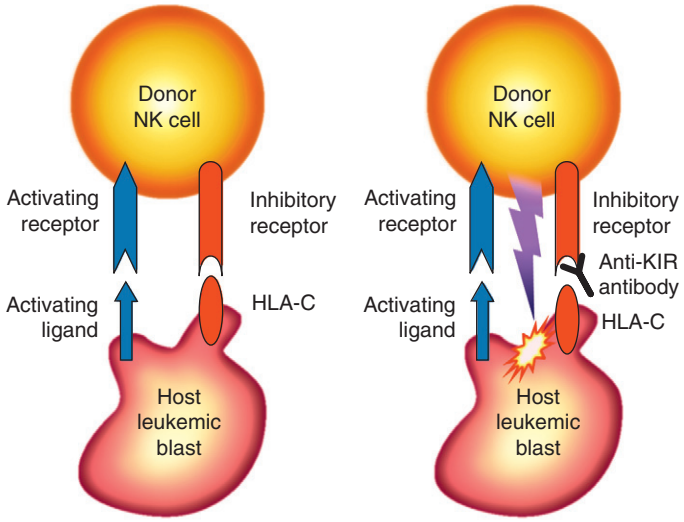

Figure 20-4 SIMPLIFIED REPRESENTATION SHOWING THE GENERAL EQUILIBRIUM BETWEEN ACTIVATING AND INHIBITORY SIGNALING THAT FAVORS NO KILLING AS SHOWN ON THE LEFT. However, the introduction of an antibody to the inhibitory receptor tips this balance towards activation and elimination of the target cell, as shown on the right. *HLA-C,* Human leukocyte antigen C; *NK,* natural killer. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: New biology and insights into the graft-versus-leukemia effect.* Blood *100:1935, 2002.)*

efficacy of cancer immunotherapy.[114,115] In fact, phase 1 clinical trials of anti-KIR antibodies are underway in humans. Fig. 20-4 demonstrates this principle.

In complementary fashion, other approaches have sought to enhance activating NK receptors, such as NKG2D. One group has created a novel bivalent protein (ULBP2-BB4) which recognizes NKG2D and CD138, a protein overexpressed in a number of malignancies, including multiple myeloma. Although such an approach is limited by knowledge of particular tumor antigens, the concept of enhancing NK function was demonstrated in this model through increases in NK cytokine secretion as well as abrogation of tumor cell growth in the presence of the molecule.[116]

Finally, the use of monoclonal antibodies directed against tumor cell antigens has significantly advanced treatment of some malignancies. For example, treatment with the monoclonal, immunoglobulin G (IgG), chimeric anti-CD20 antibody rituximab has been shown to improve survival of patients with non-Hodgkin lymphoma. As discussed, genotypic, single nucleotide polymorphisms in the FcγRIIIA (CD16) receptor expressed on NK cells and other immune cells may convey functional differences in the receptor that have clinical consequences. Patients with the V/V homozygous state at residue 176 have a higher affinity for the Fc portion of the rituximab, and these patients show enhanced clinical response to the antibody.[117] Such a finding supports the notion that enhanced ADCC function in CD16-bearing cells, including NK cells, is one key mechanism of action of rituximab and suggests that antibody-mediated cancer therapies could be advanced by enhancing NK cell numbers and cytotoxic potential in vivo.

FUTURE DIRECTIONS

Natural killer cells are a critical cellular component of innate immunity. Rapid secretion of powerful immunomodulatory cytokines and chemokines support the role of NK cells as "first responders" to immune insults, facilitating mobilization and tailoring of the innate and adaptive immune response. Potent natural cytotoxicity, unrestricted by classical antigen presentation, and costimulation required for adaptive immune cells, suggest that NK cells have an important, complementary role to that of cytotoxic T lymphocytes, which provide antigen-specific cytotoxicity and lasting memory. Further understanding of the functional differences between $CD56^{dim}$ and $CD56^{bright}$ subsets, their cytotoxicity and cytokine receptor expression, and their developmental biology will certainly shed more light on the therapeutic potential for NK cells in the pathogenesis, prevention, and treatment of human disease.

CHAPTER 21

DENDRITIC CELL BIOLOGY

Olivier Manches, Viswanathan Lakshmanan, Zbigniew M. Szczepiorkowski, and Nina Bhardwaj

Dendritic cells (DCs) are a sparsely distributed population of bone marrow (BM)–derived mononuclear cells that exist in an "immature" form in virtually all tissues in the body.[1] DC serve as professional antigen-presenting cells (APCs) with an extraordinary capacity to stimulate naïve T lymphocytes (as well as B, natural killer [NK], and NK T cells) and initiate primary immune responses. In their immature state, DCs detect and capture "danger signals" originating from microorganisms or their macromolecular constituents in their resident tissues. Upon encountering such danger signals, DCs undergo a complex series of events leading to their "maturation."[1] Maturation of DCs is characterized by migration of DCs to draining lymph nodes and processing and presentation of antigens in the context of antigen presenting molecules such as major histocompatibility complex (MHC) and CD1 to naïve T, B, and NK cells. This chapter provides a snapshot of our current understanding of DC function as well as DCs' potential clinical applications as immunotherapeutic agents in diseases such as cancer, HIV and autoimmunity.[2]

DENDRITIC CELL SUBSETS AND DEVELOPMENT

Extensive research has demonstrated that DCs exist in many "flavors."[3,4] However, our understanding of DC differentiation and the different DC subsets is complicated by the heterogeneity of data obtained from in vitro human and mouse studies and in vivo animal studies and limited in vivo human studies. The generation of functionally distinct DC subtypes follows two generally accepted models: (1) the functional plasticity model postulating the existence of a single DC lineage possessing functional plasticity and (2) the specialized lineage model postulating the existence of multiple DC lineages displaying functional diversity.[5] Both models assume four stages of DC development, namely hematopoietic precursors, DC precursors (pre-DC), immature DCs (imDCs), and mature DCs (mDCs) (Fig. 21-1). It is likely, however, that elements of both models are involved in DC subset development. In this chapter, we concentrate on human DCs with little reference to murine models. Readers are encouraged to seek additional information in several comprehensive reviews.[5-14]

Most studies on the developmental origin of human DC subsets have used in vitro culture systems. DC precursors and imDCs, similar to other cell types in the immune system, are continuously produced in a steady rate and pathogen-independent manner from $CD34^+$ hematopoietic stem cells (HSCs) within the BM. Fms-like tyrosine kinase-3 ligand (Flt-3-L) and granulocyte colony-stimulating factor (G-CSF) represent the key DC growth and differentiation factors.[15] The $CD34^+$ HSC differentiate into hypothetical common lymphoid progenitors (CLPs) and common myeloid progenitors (CMPs) in the BM. Subsequently, CMPs differentiate into $CD34^+CLA^+$ and $CD34^+CLA^+$ populations (CLA, skin homing receptor cutaneous lymphocyte-associated antigen), which give rise to phenotypically distinguishable $CD11c^+CD1a^+$ and $CD11c^+CD1a^+$ immature DCs, respectively.[16] The former migrate into the skin epidermis and differentiate into Langerhans cells, and the latter localize to skin dermis and other tissues and become interstitial imDCs.[17] The human Langerhans cell DC subset has distinct markers, including the presence of Birbeck granules; the expression of CD1a; and langerin, a member of the C-type lectin family of receptors involved in the uptake of pathogens.[18]

The $CD34^+$ hematopoietic progenitor cells (HPCs) and blood monocytes are commonly used as precursor cells for generating DC in culture in vitro for both research and immunotherapeutic purposes. HPCs are treated with c-kit ligand and tumor necrosis factor-α (TNF-α) that yield subsets of myeloid DCs, including Langerhans cells. Monocytes, obtained by simple adherence of HPCs to plastic, when exposed to a combination of GM-CSF and interleukin-4 (IL-4), yield imDCs that are comparable to some degree to tissue interstitial DCs. Maturation of these different DCs can be induced by the addition of various stimuli.

The pre-DC subset expresses several myeloid markers, including CD11b, CD11c, CD13, CD14, and CD33, indicating that they may derive from a CMP. In contrast to the blood "myeloid DCs" derived from CMP, which we will refer to here as conventional DCs (cDCs), the "plasmacytoid DCs" contain "lymphoid" mRNA transcripts for pre-T α chains, germline IgK, and Spi-B and are also called interferon (IFN) type I producing cells (IPCs). These latter cells display distinct plasma cell morphology, contain abundant endoplasmic reticulum (ER), and express CD4 and high levels of the IL-3αR but lack myeloid antigens, including CD11c and most lineage markers. Plasmacytoid DCs (pDC) are found in peripheral blood, thymus, and many lymphoid tissues. The production of extraordinarily high levels of IFN type 1 by pDC is unique to this cell type and may be important for initiating a strong antiviral innate response and promote maturation of bystander $CD11c^+$ cDC to protect them from the cytopathic effect of viruses.[18-21] It is hypothesized that human cDCs and pDCs have evolved to recognize and respond to different pathogens in unique ways owing to their complementary expression of receptors for "pathogen-associated molecular patterns" (see Antigen Acquisition section), capacity to secrete either IFN type I or IL-12, antigen presentation, and migration into secondary lymphoid organs. As mentioned, pDCs secrete high amounts of IFN-α upon viral infection but no IL-12 and display poor antigen capture and presentation capacity. Upon activation, pDCs differentiate into cells bearing similar characteristics to activated cDCs (i.e., with a dendritic morphology, high expression of MHC class II molecules, and the capacity to prime naïve T cells)[22,23] but express low levels of CD11c and lack typical myeloid markers. The functional properties of these latter pDC-derived DC is still to be investigated thoroughly,[24] although they may differ from cDCs, especially in their cross-presentation[25] or T-cell skewing capacities. Thus, whereas DCs derived from pDCs upon culture with IL-3 and activation by CD40-L preferentially prime naïve $CD4^+$ T cells toward a Th2 profile, DCs derived from pDCs by viral/Toll-like receptor (TLR) stimulation prime toward a Th1 profile in an IFN-α–dependent and IL-12–independent pathway.[20] Upon activation, immature cDCs migrate through afferent lymph from nonlymphoid tissues to the T cell–rich areas of lymph nodes. Plasmacytoid DCs, which also migrate into T-cell areas of secondary lymphoid tissues, do so through high endothelial venules (HEVs) of lymph nodes and marginal zone of the spleen, likely using CCR7 and CD62-L.[26] Both activated blood cDCs and pDCs can migrate in response to lymph node homing chemokines (CCL19 and

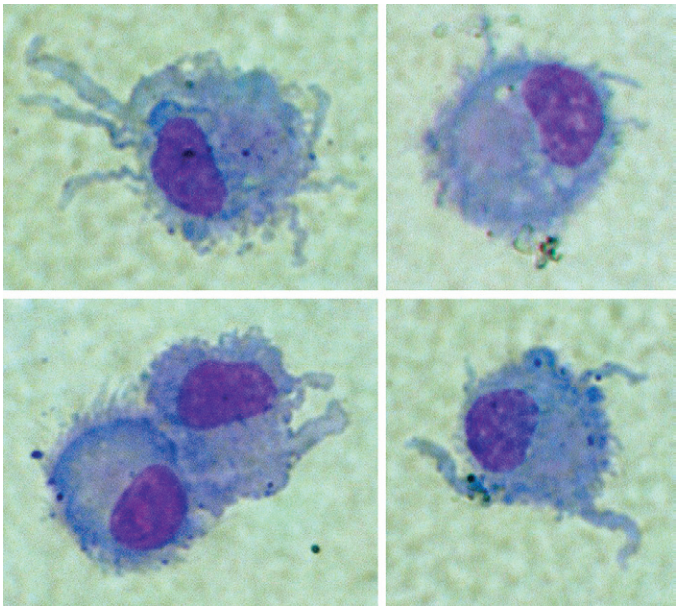

Figure 21-1 EXAMPLES OF MONOCYTE-DERIVED MATURE DENDRITIC CELLS. The mononuclear cells were enriched by adherence, cultured with interleukin-4 (IL-4) and granulocyte colony-stimulating factor (G-CSF) for 6 days and underwent maturation with IL-1, IL-6, tumor necrosis factor-α (TNF-α), and prostaglandin E_2 (PGE_2) for 24 hours.

CCL21) through expression of CCR7. Although cDCs can be found in virtually every peripheral tissue as well as in lymphoid organs, pDCs seem to display a more restricted distribution. They can be found mostly in the T-cell area of lymphoid organs (lymph node, tonsils, spleen, thymus, BM, and Peyer patches), blood, and some peripheral tissues (liver, nasal mucosa). Although cDCs and pDCs express a similar array of chemotactic receptors (e.g., CCR2, CCR5, CXCR2, CXCR4), pDCs do not respond to a number of inflammatory chemokines. However, they accumulate in inflamed tissues, such as in systemic lupus erythematosus (SLE) and contact dermatitis, probably through their expression of ChemR23 and CXCR4.

This division of DCs into cDC and pDC subsets is likely to be an oversimplified view of DC heterogeneity. For example splenic DCs are heterogenous with regard to expression of CD4, CD11b, and CD11c, but most of the thymic DCs are $CD11c^+$ but lack other myeloid markers, thereby not fitting into either of the classical categories of cDCs and pDCs in blood.[27]

An important role for $CD103^+$ (αE integrin) has recently been uncovered. $CD103^+$ DC reside in the intestinal mucosa and play a crucial role in tolerance to commensal bacteria and food antigens. These cells originate in the lamina propria (LP) and migrate to the mesenteric lymph nodes (MLNs), where they drive the differentiation of gut-homing FoxP3+ regulatory T cells by producing retinoic acid from dietary vitamin A.

In addition, the $BDCA3^+$ (CD141) DC subset has been found to be the equivalent of murine $CD8\alpha^+$ DCs, which are most potent at cross-presenting antigens to $CD8^+$ T cells. They express the chemokine receptor XCR1 and the DC NK lectin group receptor-1 (DNGR1) C type lectin, a sensor for necrotic cells, and mediate the phagocytosis of dead cells. They also express basic leucine zipper transcriptional factor ATF-like-3 and INF regulatory factor-8, which may be essential for their development. $BDCA3^+$ DCs express high levels of TLR3 and TLR8, and upon stimulation by TLR3 agonists (e.g., poly I:C), they secrete high amounts of IL-12 and IFN-β, both Th1-skewing cytokines. These combined characteristics make them attractive targets for DC-based vaccines in cancer and chronic immune diseases.

Although Langerhans cells and microglia seem to be capable of self renewal in ectodermal tissues, epidermis and brain, other DC arise from bloodborne precursors from BM. DC arise from a macrophage and DC precursor (MDC), giving rise to monocytes and DCs, and a common DC precursor (CDP).[28] Recent studies of human immunodeficiencies have highlighted the transcription factors directing the development of DCs and emphasized their role in defense against microbial pathogens. Thus, in DC, monocyte, B, and NK lymphoid deficiency (DCML), blood and interstitial DCs are absent along with monocytes and pDCs. The DCML is attributable to GATA-binding factor 2 (GATA2) mutations, a transcription factor involved in the homeostasis of HSCs. Patients with DCML deficiency have increased susceptibility to *Mycobacteria* spp., fungi, and viruses. Another DC deficiency syndrome is caused by INF regulatory factor 8 (IRF8) mutations. The autosomal recessive K108E mutations leads to defects in peripheral cDCs, pDCs, and monocytes, with increased susceptibility to *Mycobacteria* spp., other intracellular bacteria, and viruses and is accompanied by a myeloproliferative syndrome. The dominant sporadic mutation T80A induces a specific loss of $CD1c^+$ DC, with increased susceptibility to mycobacterial infection but otherwise a normal life expectancy.

The developmental origin of pDCs versus cDCs is still debated because pDCs and cDCs can be derived from both CLP and CMP, suggesting that pDCs and cDCs may arise during hematopoiesis from progenitors with already distinct and restricted lineage potential.[29] It seems that whereas cDC differentiation is dependent on the transcription factor Ikaros, pDC development is dependent on the Ets family transcription factor SpiB and probably PU.1. A recent study also described an important role for the upregulation of basic helix–loop–helix transcription factor (E-protein) E2-2 in developing pDCs, and E2-2–deficient hematopoietic progenitors do not produce pDC.[30] Studies in mice described the conversion of BM pDCs into cDCs upon viral infection, again highlighting the complexity and plasticity of DC development.[31]

The migration of myeloid DC and plasmacytoid DC precursors from the BM can be increased by administration of Flt-3-L up to 50-fold for pre-DCs and 15-fold for pDCs.[32,33] G-CSF is also known to increase the number of pDCs in the circulation. With the advent of newer technologies, it has also become feasible to generate large numbers of DC subsets in vitro.

THE CONCEPT OF MATURATION

In their resting state, imDCs are primed to acquire antigens in situ through a variety of receptors and mechanisms. Upon encountering pathogens or other "activating stimuli," DCs undergo a complicated series of phenotypic and functional changes referred here to as "activation" and "maturation," respectively.[1] The process of DC activation is an intricate differentiation process under tight control that is closely associated with antigen acquisition. It is induced by various stimuli (Table 21-1) or danger signals (e.g., signs of pathogenic infection or cell injury), including cytokines (e.g., IFN type I, TNF-α, and IL-1), microbial products (e.g., lipopolysaccharide [LPS], flagellin), intracellular products (e.g., heat shock proteins), growth factors (e.g., thymic stromal lymphopoietin [TSLP]), immune complexes and T-cell molecules (e.g., CD40). The process of activation is characterized by upregulation of adhesion and costimulatory molecules such as CD54, CD80, CD86, MHC class I and II molecules, cytokines (e.g., TNF-α, IL-12, IL-18) and chemokines (e.g., RANTES, MIP-1α, IP-10). The latter enable the recruitment of T cells, monocytes, and other DCs into the local environment. In their mature state, DC express markers, which distinguish them from imDCs such as CD83 (a molecule involved in thymic T-cell selection and DC–DC interactions) and DC-LAMP, a lysosomal protein. Maturation also changes the migratory properties of DCs. They express CCR7 and acquire responsiveness to the chemokines CCL19 and CCL21 that are expressed in the T-cell areas of lymph nodes where mature DCs generate immune responses. Concomitantly, DCs downregulate their receptors for CCL3, CCL4, and CCL5, which are secreted at sites of inflammation, reduce their capacity for phagocytosis, macropinocytosis, antigen uptake, and processing but acquire potent immunostimulatory ability through enhanced T-cell–DC immune synapse

Table 21-1 Agents That Cause Dendritic Cell Maturation*

Agent Property	Molecules
Stimulatory agents	TNF family members (TNF-α, CD40L, FasL, TRANCE) TLR ligands (dsRNA, LPS, imiquimod, CpG ODNs) Growth factors (TSLP) Interferons (IFN-α) Adhesion molecules (CECAM-1 (CD66a) Costimulatory molecules (LIGHT, B7-DC) Receptors (FcR via Ag-Igs; TREM-2 via Dap-12) Viruses or microbes (influenza, bacteria, bacterial products) Chemokines (MCP, MIP1α, RANTES, IP10, IL-8, MDC, TARC) Chemokine receptors (CCR7 and loss of CCR2 and CCR5)
Inhibitory agents	Drugs (rapamycin, FK506, cyclosporin A, dexamethasone, IVIg) Chemokines (IL-10) Viruses (EBV, vaccinia, canarypox, HSV) Others (β2 microglobulin)
Survival signals	CD40 L, TRANCE, B7-DC, Bcl-2
Cell–cell interaction	Activated cells (CD4 and CD8 cells [via CD40L]) NK cells, NK T cells Vδ1+, γδ T cells

Ag-Igs, Antigen-immunoglobulin immune complexes; *Bcl-2,* B-cell lymphoma 2; *CCR,* chemokine (C-C motif) receptor; *CECAM-1,* carcinoembryonic antigen-related cell adhesion molecule-1; *CpG ODNs,* CpG oligodeoxynucleotides; *dsRNA,* double-stranded DNA; *EBV,* Epstein-Barr virus; *FcR,* Fc receptor; *HSV,* herpesvirus; *IFN,* interferon; *IL,* interleukin; *IP10,* interferon gamma-induced protein 10; *IVIg,* intravenous immunoglobulin; *LIGHT,* homologous to lymphotoxins, exhibits inducible expression, and competes with HSV glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes; *LPS,* lipopolysaccharide; *MCP,* macrophage/monocyte chemotactic protein; *MDC,* macrophage and dendritic cell precursor; *MIP1α,* macrophage inflammatory protein 1 alpha; *NK,* natural killer; *RANTES, regulated* on activation, normal T expressed and secreted; *TARC,* thymus and activation-regulated chemokine; *TNF,* tumor necrosis factor; *TRANCE,* TNF-related activation-induced cytokine; *TREM-2,* triggering receptor expressed on myeloid cells 2; *TSLP,* thymic stromal lymphopoietin.
*Maturation is a complex process tightly linked to antigen acquisition and the surrounding microenvironment. See text for more details.

Table 21-2 Antigen Recognition and Uptake Receptors Expressed by Dendritic Cells*

Receptor	Antigenic Ligand
C-type lectins (DC-SIGN, MMR, DEC-205)	Mannosylated molecules, viruses, bacteria, fungi
FcγR (CD32, CD64)	Immune complexes, antibody-coated tumor cells
CD1 a, b, c, d	Biphosphonate moieties in *Mycobacterium tuberculosis,* BCG, and *Listeria monocytogenes;* lipid and glycolipid foreign and self-antigens
Integrins (αVβ5, CR3, CR4)	Opsonized antigens, apoptotic cells
Scavenger receptors (CD36, LOX-1)	Opsonized antigens, apoptotic cells, heat shock proteins
TLRs and other PRRs	TLR 2–8 (myeloid DC) peptoglycans, endotoxin, flagellin TLR 7 (plasmacytoid DC) bacterial DNA; RIG-I, MDA5, STING, DAI, AIM2, PKR, NOD proteins
HSP-R (CD91)	Heat shock proteins
Aquaporins	Fluids

AIM2, Absent in melanoma 2; *BCG,* Bacillus Calmette-Guérin; *DAI,* DNA-dependent activator of IFN-regulatory factors; *DC,* dendritic cell; *DC-SIGN,* dendritic cell-specific intercellular adhesion molecule-3-Grabbing non-integrin; *HSP-R,* heat shock protein receptor; *MDA5,* melanoma differentiation-associated protein 5; *NOD,* nucleotide oligomerization domain; *PKR,* protein kinase R; *PPR,* pattern recognition receptor; *RIG-1,* retinoid-inducible gene I; *STING,* stimulator of interferon genes; *TLR,* Toll-like receptor.
*The table lists some of the receptors expressed by DCs that are involved in antigen acquisition. The antigen receptor repertoire dictates that range of antigens captured by the DC. Ligation of some of these receptors induces DC maturation.

formation, production of immunoproteosomes, and upregulation of unique DC-specific costimulatory molecules such as B7-DC.[34] However, although increased expression of costimulatory molecules and migration to secondary lymphoid organs often correlates with their capacity to prime CD4 and CD8 immunity, activated DCs may also induce tolerization of T cells, as when $CD4^+$ T cell help is missing[35,36] or on activation by inflammatory cytokines in the absence of TLR engagement,[37] and can potentially induce the generation of regulatory T cells (Tregs). Some stimuli, such as thymic stromal lymphopoietin (TSLP), can induce phenotypic maturation of DCs without concomitant secretion of proinflammatory cytokines such as IL-12, IL-6, TNF-α, or IL-1.[38] Therefore, DC maturation is more appropriately used in a functional sense, with mature DCs being defined as able to prime naïve T-cell responses. What makes a phenotypically activated DC capable of priming instead of tolerizing a T cell appears multifactorial and dependent on such factors as the state of the microenvironment and the DC subset in question, although this remains to be clearly defined.

ANTIGEN ACQUISITION AND DENDRITIC CELL ACTIVATION

Immature DCs sample their environment through several mechanisms, including micropinocytosis, macropinocytosis, receptor-mediated endocytosis, and phagocytosis. They display an array of surface receptors, which facilitate acquisition of antigens and pathogens and at the same time induce differentiation into activated DCs. An important class of receptors is the pattern recognition receptors (PRRs), which recognize pathogen-associated molecular patterns (PAMPs) expressed by many microorganisms. PRRs serve as an important link between innate and adaptive immunity because they directly mature DCs while also inducing the production of a variety of cytokines and chemokines. PRRs consist of several groups of receptors, including secreted (e.g., MBL, CRP, SAP, LBP), cell-surface (e.g., CD14, MMR, MSR, MARCO),[39] and intracellular molecules (e.g., RIG-I and MDA5, which are RNA helicases involved in the recognition of nucleic acids upon viral infection; STING, DAI, AIM2 [absent in melanoma 2], which recognize intracellular DNA[40]; NOD receptors, which recognize peptidoglycan subcomponents or other bacterial molecules; inflammatory caspases, such as caspase-1 and caspase-5, which form an intracellular complex with NALP1 or NALP2 and NALP3 called the inflammasome that recognize bacterial RNA and other danger signals and induce the production of the proinflammatory cytokines IL1β and IL-18) (Table 21-2). TLRs, which constitute another group of PRRs, are expressed by imDCs and mediate activation by microbial components such as peptidoglycan, LPS, flagellin, and unmethylated CpG DNA motifs. Ligation of the TLRs results in the activation of Rel family members, particularly the transcription factor nuclear factor kappa-B (NF-κB), c-Jun-terminal kinase (JNK), and p38 MAP kinase, leading to the initiation of the maturation process.[41,42] TLRs are unevenly distributed among DCs, with myeloid DCs expressing TLR 2, 3, 4, 5, 8 and plasmacytoid DC strongly expressing TLR 7 and 9 (Table 21-3). Another important feature of some TLRs is their capacity to induce secretion of IFN type I for antiviral defense and immune regulation. cDCs express TLR3 and 4, mediating recognition of viral double-stranded

Table 21-3 Toll-Like Receptors Expressed by Dendritic Cells*

mDC	pDC	Ligand(s)
TLR1	TLR1	?
TLR2		Peptidoglycan *(Staphylococcus aureus)* Lipoproteins and lipopeptides from several bacteria Glycophopshotidylinositol anchors from *Trypanosoma cruzi* Lipoaminomannan from *Mycobacterium tuberculosis* Zymosan (yeast)
TLR3		Double-stranded RNA (e.g., poly I:C)
TLR4		LPS + MD-2, taxol, hsp 60 (?), heparan sulfate (?), RSV, fibronectin
TLR5		flagellin (*Salmonella typhimurium, Listeria* spp.)
TLR6	TLR6	? or undergoes dimerization with TLR2
	TLR7	Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
TLR8	TLR8	Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
	TLR9	CpG ODNs, DNA from bacteria and viruses, chromatin-IgG complexes
	TLR10	?

CpG ODNs, CpG oligodeoxynucleotides; *RSV,* respiratory syncytial virus.
*Toll-like receptors (TLRs) can form heterodimeric receptor complexes consisting of two different TLRs or homodimers (as in the case of TLR4). The TLR4 receptor complex requires supportive molecules (MD-2) for optimal response to its ligand lipopolysaccharide (LPS). A common feature of the TLR receptors is the cytoplasmic TIR domain that serves as a scaffold for a series of protein–protein interactions that result in the activation of a unique signaling module consisting of MyD88; interleukin-1 receptor associated kinase (IRAK) family members; and Tollip, which is used exclusively by TIR family members. Subsequently, several central signaling pathways are activated in parallel, the activation of nuclear factor kappa-B (NF-κB) being the most prominent event of the inflammatory response. Recent developments indicate that in addition to the common signaling module MyD88/IRAK/Tollip, other molecules can modulate signaling by TLRs, especially of TLR4, resulting in differential biologic responses to distinct pathogenic structures. TLR2 is also involved in cross-presentation.

RNA and LPS, respectively, and on triggering secrete low amounts of IFN-β through a signaling pathway using the adaptor TRIF and the transcription factor IRF3. Although cDCs can also induce IFN type I through RIG-I and MDA-5 upon viral infection, pDCs seem to rely mostly on a specialized MyD88-dependent signaling pathway, allowing them to secrete very high amounts of IFN-α upon triggering of TLR7 and 9. This is because of their constitutive high expression of IRF7, a crucial IFN-α gene transcription factor, and because of a specialized spatiotemporal regulation of TLR7 and 9 signaling, allowing IRF7 to interact with MyD88 docked onto TLR in the endosomal membrane.[43]

The inflammasome consists of a family of PRRs that induce IL-1 and IL-18 secretion. IL-1β secretion can be triggered through the NLRP3, NLRC4, and NLRP1 inflammasomes, as well as by the DNA sensor AIM2. Activation of the inflammasome occurs through activation of the nucleotide-binding domain, leucine-rich repeat-containing proteins (NLRs). NLRs are composed of three domains: at the N-terminus a pyrin domain, a caspase recruitment domain, or a baculovirus inhibitory repeat domain; the central domain is the nucleotide binding domain (NBD) responsible for dNTPase activity and oligomerization; and the leucine-rich repeat domain at the C-terminus. IL-1 and IL-18 secretion is dependent on synthesis of pro-IL-1 and pro-IL-18, which can be induced in response to TLR-NF-κB signaling. Activation of the inflammasome leads to caspase-1–mediated processing of pro-IL-1 and pro-IL-18 for IL-1β or IL-18 secretion and inflammatory cell death (pyropoptosis and pyronecrosis). The inflammasome can be activated by sterile (nonmicrobial) activators, including host (adenosine triphosphate [ATP], uric acid crystals, amyloid β) and microenvironment derived molecules (alum, silica, asbestos). It can also be activated by pathogen-derived products, including PAMPs. Microbial activators include pore-forming toxins, RNA and DNA, flagellin, β-glucans, and zymosan. The best studied inflammasome is the NLRP3 inflammasome, and the mechanisms of activation are being deciphered. It is believed that inflammasome activation can occur through three main mechanisms: generation of reactive oxygen species (ROS), possibly by the phagosomal NADH (nicotinamide adenine dinucleotide) oxidase, release of cathepsin B upon phagolysosomal destabilization, and pore formation at the plasma membrane through the P2X7 receptor, allowing K+ efflux.

C-type lectins are calcium-dependent carbohydrate-binding proteins with a broad range of biologic functions, many of which are involved in immune responses. They are well represented on DCs and include the following: DC-SIGN, responsible for binding of HIV-1, HIV-2, simian immunodeficiency virus, Ebola viruses, dengue virus, *Candida* spp., *Leishmania* spp.; blood dendritic cell antigen 2 (BDCA-2), potentially responsible for delivering tolerogenic signals; BDCA-4/neuropilin-1, capable of binding vascular endothelial growth factor (VEGF); langerin, responsible for uptake and processing of antigens in Langerhans cells; DEC-205 (CD205) involved in the uptake and processing of antigens in MIIV (vesicles enriched for MHC class II molecules and proteases such as the cathepsins that mediate antigen processing and MHC class II peptide complex formation), and generation of tolerogenic signals; and macrophage mannose receptor (MMR), which is involved in the processing of microbial organisms.

Other receptors expressed by DCs include FcR, which is involved in cross-presentation of immune complexes and antibody opsonized dead cells; integrins such as αVβ5, scavenger receptors CD36, and Mer-family tyrosine kinases for phagocytosis of apoptotic cells and lipoxygenase-1 (LOX-1) or CD91 for uptake of heat shock proteins (HSPs); complement receptors that play a role in uptake of opsonized microbes and apoptotic cells; receptors for viruses (e.g., CD4, CCR5, and CXCR4 for HIV and CD46 for measles virus); and the CD1 family of receptors that activate CD4, CD8, γδT cells, and NK T cells through binding and processing of antigens such as sphingolipids, sulfatides, glycosphingolipids glycosylphosphatidylinositol (GPI)-anchored mucin-like glycoproteins (GPI mucins), glycoinositolphospholipids (GIPLs), and their phosphatidylinositol moieties. Altogether, these various receptors provide substantial avenues for DCs to efficiently capture multitudes of antigens in their environment.

Antigen capture is tightly coupled to DC activation and antigen presentation, and triggering of TLR or exposure to inflammatory cytokines first induces a transient increase in the macropinocytic uptake followed by a near complete downregulation of the uptake process. Furthermore, it has been suggested that TLR engagement also enhances microbe-loaded phagosome maturation, potentially discriminating between nonimmunogenic antigens (apoptotic cells) and microbial antigens at the antigen processing level.[44]

ANTIGEN PROCESSING

Dendritic cells have a remarkable ability to process and present antigens restricted by major histocompatibility complex (MHC) and CD1 molecules. The processing is tightly associated with DC activation.

Major Histocompatibility Complex Class I Antigen Presentation (Endogenous Route)

The process of antigen processing and presentation to $CD8^+$ T cells begins with degradation of proteins synthesized within the cytoplasm, either as mature proteins or as neosynthesized defective proteins (defective ribosomal products [DRiPS]), into oligopeptides by the ubiquitin–proteasome pathway. Misfolded proteins are also a

source of antigenic peptides after retrotranslocation from the ER to the cytosol through the ER-associated degradation (ERAD) pathway. Subsequently, aminopeptidases cleave N-terminal precursors into peptides of appropriate length for presentation on MHC class I molecules. Antigen processing via this route is regulated through activation of the catalytically active subunits of the proteasome, the PA28 proteasome activator, and leucine aminopeptidase, which are upregulated by IFN.[45] Mature DCs, in particular, express immunoproteosomes containing the active site subunits latent membrane protein 2 (LMP2), LMP7, and MECL-1, which can enhance antigen processing.[46] After transport into the ER through the transporter associated with antigen processing (TAP) (Fig. 21-2), long peptides are further trimmed by ER aminopeptidase-1 (ERAP-1) to 8-mer or 9-mer peptides for loading onto MHC class I molecules.

Dendritic cells also have the capacity to acquire antigens exogenously and process them for presentation on MHC class I molecules. This phenomenon, referred to as *cross-presentation,* allows the immune system to recognize antigens that are not otherwise presented or that may not access DCs directly (e.g., tumor cells, viruses). DCs can acquire such antigens in the form of apoptotic cells, necrotic cells, antibody opsonized cells, immune complexes, and heat shock proteins (intracellular chaperones for antigenic peptides, which are released by necrotic cells).[47] DCs even acquire antigens via phagocytosis of particles released from intracellular vesicles (referred to as *exosomes*).[48] Finally, DCs may even nibble bits of live cells to acquire antigens.[49] Mechanistically, cross-presentation may involve cathepsin-S dependent processing of antigenic peptides within the endocytic/phagocytic vacuole and subsequent binding to recycling MHC class I molecules within the same organelle (vacuolar pathway) (see Fig. 21-2).[50] Alternatively, the antigens may be transferred from the endocytic vacuole to the cytoplasm followed by processing by the proteasome and loading onto newly formed MHC class I molecules (phagosome-to-cytosol pathway), with a possible recruitment of the ER machinery for antigen processing and MHC class I loading (see Fig. 21-2).[51-54] Activation of DCs through TLR triggering or exposure to fever-like temperatures induces transient formation of large polyubiquitinated protein aggregates called DC aggregosome-like induced structures (DALIS), the role of which might be to temporarily concentrate and store endogenous antigens to reduce self-antigen presentation.[55,56] This phenomenon of cross-presentation is especially efficient in, if not unique to, DCs compared with other APCs.

Major Histocompatibility Class II Antigen Presentation (Exogenous Route)

Assembly of MHC class II molecules, which present antigen in the form of short peptides to $CD4^+$ T lymphocytes, occurs in the ER of DC. After being assembled, these MHC class II molecules are transported to specialized compartments in the lysosomal system involved in the processing of exogenous antigens. These include MIIVs, which are protease rich compartments containing newly synthesized MHC class II molecules. Epidermal DCs or Langerhans cells contain cytoplasmic tubules with internal striations called *Birbeck granules*. Birbeck granules are rich in langerin (CD205), a C-type lectin necessary for granule formation and possibly for capture of pathogens.[57] After being endocytosed by imDCs, antigens are partially retained within lysosomes. Upon receiving a maturation signal, the pH of lysosomes decreases to less than 5 (owing to the activation of a vacuolar H^+ ATPase). Concomitantly there is antigen degradation caused by activation of proteases such as cathepsins. Cystatin C, a protein that blocks the activity of cathepsin S, is also degraded, thereby allowing the degradation of invariant chain peptide (Ii chain), which

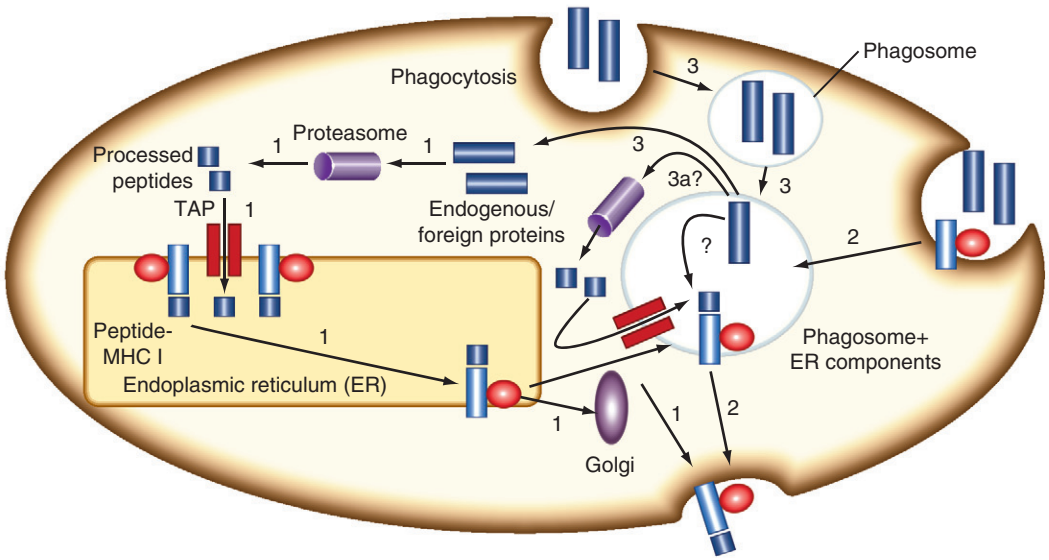

Figure 21-2 PATHWAYS FOR MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) CLASS I PRESENTATION. The classical pathway for MHC class I presentation *(1)* involves degradation of endogenous or viral antigens into peptides by the proteasome followed by transport into the endoplasmic reticulum (ER). After further trimming in the ER, the peptides are loaded onto newly synthesized MHC class I molecules, and the peptide–MHC class I complexes are transported to the plasma membrane. Two main pathways of cross-presentation *(2, 3)* have been described that allow presentation of exogenous antigens in association with MHC class I molecules. Antigens endocytosed or phagocytosed can be cleaved into peptides by proteases and loaded onto recycling MHC class I molecules within the same phagosome or on the cell surface (vacuolar pathway) *(2).* Alternatively, antigens may escape from the phagosome and enter the cytosol (phagosome-to-cytosol pathway) *(3)* to be processed via the classical MHC class I pathway. It has been suggested recently that elements of ER can be associated with phagosomes, allowing transfer of antigens into the cytosol by the ER-associated degradation (ERAD) pathway and degradation by the phagosome-associated proteasome *(3a).* The importance of each pathway *(2, 3)* for cross-presentation in vivo and the precise mechanisms and the locations of antigen processing in each model are under investigation. *TAP,* Transporter associated with antigen processing.

normally blocks access of antigenic peptides to MHC class II molecules. These changes occur in late endosomes and lysosomes (the MIIV compartment). After antigenic peptide is bound to MHC class II molecules, they exit the lysosomes through the formation of long tubular structures, which simultaneously deliver costimulatory molecules such as CD86 to the cell surface.[58,59]

Dendritic cells handle internalized antigens in a specialized way unlike other phagocytic cells such as macrophages, which degrade most of the internalized material, leaving only limited amounts of antigenic peptides for presentation onto MHC molecules. On the contrary, internalized antigens in cDCs are preserved for longer times, thereby allowing their transport by maturing DC to secondary lymphoid organs, where actual presentation occurs. Mature DCs display higher levels of proteolysis than imDCs, allowing appropriate degradation of the antigens for loading onto MHC molecules. These differences are accounted for by several features unique to DCs, such as low levels of lysosomal proteases in immature stages compared with macrophages, expression of protease inhibitors (cystatin C), regulation of lysosomal pH (and hence activity of proteases) by regulation of the acidifying V-type H+ ATPase activity, and consumption of H^+ upon reaction with superoxide radicals generated by NADPH (nicotinamide adenine dinucleotide phosphate) oxidase NOX2 in maturing DCs.[60] During maturation, trafficking of MHC class II molecules to the surface is dramatically increased, probably because of degradation of Ii chain (containing endosome-lysosome targeting signal) in acidic compartments, leading to transport of MHC class II via the constitutive secretory pathway to the cell membrane.

In addition to direct presentation of intracellular antigens and cross-presentation of internalized material, DCs can acquire preformed MHC class I molecules in complex with antigens from other cells by the process of trogocytosis (transfer of cell-membrane patches or individual proteins between cells) or through gap junctions, in a process termed *cross-dressing;* this allows rapid presentation without processing of antigens. It has been suggested that memory CD8 T cells are preferentially activated by this mode of presentation in contrast to naïve T cells.[61] It furthers provides a mechanism for antigen transfer between DC populations, which can be exploited for vaccine design. Thus, it has been shown that ex vivo loaded DC sometimes do not directly activate host CD8+ T cells, which rather requires transfer of peptide–MHC complexes from vaccine DC to resident DC for efficient priming.[62]

Table 21-4 Costimulatory Molecules Involved in the Interaction Between Dendritic Cells and T Cells (Signal 2)*

Dendritic Cell	T Cell	Signal
B7 FAMILY		
B7-1(CD80)/B7-2(CD86)	CD28	Activating
B7-1(CD80)/B7-2(CD86)	CTLA4	Inhibitory
B7-H1(PDL1)/B7-DC(PDL2)	?	Activating
B7-H1(PDL1)/B7-DC(PDL2)	PD1	Inhibitory
B7-H2 (B7h; B7PR1; ICOSL)	ICOS	Activating
B7H3	?	Activating
B7H4 (B7S1; B7x)	?	Inhibitory
TNF RECEPTOR FAMILY		
4–1BBL	4–1BB	Activating
CD27L	CD27	Activating
OX40L	OX40	Activating
LIGHT	LIGHT-R	Activating
CYTOKINES		
IL-2	IL-2R	T-cell proliferation
IL-12	IL-12R	T-cell proliferation
IL-18		

From Moretta A: Natural killer cells and dendritic cells: Rendezvous in abused tissues. *Nat Rev Immunol* 2:957, 2002.
CTLA, Cytotoxic T-lymphocyte antigen 4; *IL,* Interleukin; *LIGHT,* homologous to lymphotoxins, exhibits inducible expression, and competes with HSV glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes; *PD1,* programmed death 1; *TNF,* tumor necrosis factor.
*T-cell activation requires two signals. The T-cell receptor interaction with a peptide–MHC complex (signal 1) is accompanied by signal 2 delivered by one of the mechanisms listed in this table. Formation of the immunologic synapse between a dendritic cell and a T cell determines the fate of the lymphocyte. The number of identified costimulatory molecules responsible for signal 2 is increasing steadily.

T-CELL ACTIVATION

T-cell activation systematically requires three signals. Signal 1 is generated by the T-cell receptor (TCR) after engagement by a peptide–MHC complex on the APC. Signal 2 or costimulatory signals, determines qualitative and quantitative elements of T cell activation and differentiation and is required for priming of naïve T cells. Signal 3 specifies the type of response to be mounted, inducing either Th1 or Th2 differentiation in CD4 T cells or promoting a regulatory phenotype. MHC–peptide, costimulatory molecules, and other signaling and adhesion molecules promote DC contact with T cells via formation of an immunologic synapse that determines the duration and strength of signals transduced to T cells, leading to their subsequent activation. The minimum time for productive interaction between naïve T cells and DCs is 6 to 30 hours, with lesser time periods required for memory T-cell activation.[63,64] Although only a few peptide–MHC complexes (<10) are sufficient to trigger calcium fluxes in T cells,[65] only mature DC can prime naïve CD4 and CD8 T cells.[66] Remarkably, relatively few peptide–MHC complexes (<200) are necessary on mature DCs to activate T cells. Compared with other APCs such as B cells and monocytes, DCs are up to 1000-fold more efficient at activating T cells.[67]

Costimulatory molecules include the CD80 and CD86 members of the B7 family, which ligate to CD28 on T cells and members of the TNF family, such as CD40 (Table 21-4).[12] Notably, one new member of the B7 family, B7-DC, is unique to DC and stimulates naïve T cells highly efficiently.[68] Other molecules play inhibitory roles upon encountering their receptor on T cells. For example, programmed death ligand 1 (PDL1) on DCs interacts with PD1 on T cells to downregulate T-cell responses. ICOS-L is present on both DC and B cells and is critical for germinal center formation and immunoglobulin class switching.

Signal 3 determines the skewing of the T-cell response such that T cells may terminally differentiate toward either IFN-gamma producing $CD4^+$ T cells (Th1 cells), which eradicate intracellular pathogens (bacteria or viruses), or into Th2 cells producing IL-4, IL-5, and IL-13, which promote elimination of extracellular infections.

Additionally, cytokines such as IL-12 for Th1 or IL-4 for Th2 differentiation are crucial determinants of initiation or amplification of Th responses. It has been suggested that DCs express the Notch ligands delta or jagged under Th1 or Th2 conditions, respectively, and that these ligands promote differentiation of naïve T cells toward one or the other Th profile.[69] Thus, whereas factors and pathogens, which stimulate DC maturation and IL-12 production, promote Th1 responses (e.g., *Escherichia coli*), inducers of IL-4 production prime Th2 responses (e.g., *Porphyromonas gingivalis*).

Furthermore, the Th1 polarizing capacity of DCs depends on a number of variables that include the expression of certain transcription factors, the microenvironment, exposure to various maturation stimuli, the kinetics of maturation, and the antigen dose. For example, expression by DCs of the transcription factor T-bet, which controls IFN-γ expression in $CD4^+$ T cells, appears to be required for optimal development of Th1 responses.[70] Epithelial DCs in the respiratory tract may by default induce Th2 responses upon production of factors

such as TSLP by epithelial cells.[38] The duration of DC activation and antigen dose also determines the direction of T-cell skewing. Prolonged activation causes IL-12 depletion and results in "exhausted DCs."[34] DCs presenting low amounts of antigen skew towards Th2 whereas high doses skew toward Th1, which in turn depends on the maturation state of the DCs and consequences of environmental exposure.[71,72]

Recently, a new lineage of effector CD4 T cell was discovered.[73] Named Th17 because of their characteristic secretion of IL-17, this lineage of cells is implicated in several chronic inflammatory disorders. The IL-12 family member IL-23 and transforming growth factor β (TGFβ) have been implicated in the generation of Th17 cells, but the precise role of DCs in the formation of these cells remains to be determined.[73] LPS-stimulated DCs secrete inflammatory cytokines, notably IL-6, and in combination with TGFβ seem to divert differentiation of Tregs into Th17 cells.[74,75] TGFβ upregulates the expression of the pivotal transcription factor RORγt in a concentration-dependent manner, but high TGFβ concentration favors Treg development over Th17 differentiation, partly through Foxp3 inhibitory interaction with RORγt.[76] The pathogenic role of Th17 may depend on the cytokine milieu in which they are differentiated or expand, and DC-derived IL-23 or IL-1β could contribute to enhanced pathogenicity of TH17 cells. On the other hand, Th17 cells display heightened levels IL-10 receptor and are more susceptible to IL-10–mediated regulation, a cytokine secreted by DC upon ligation of some TLRs (e.g., TLR2, TLR4). Therefore, the flexibility of DC activation and cytokine secretion profile may impact on the pathogenic potential of developing Th17 cells.

It is important to note that T-cell priming depends on mDCs because imDCs may induce immunosuppressive or Tregs.[77,78] In fact, antigen presentation by imDCs in vivo is an important pathway by which tolerance is maintained at both the CD4 and CD8 T-cell level, either through the induction of Tregs or through the deletion of autoreactive T cells.[79] Nevertheless, recent data suggest that in some conditions, mDCs can also induce the generation of $CD4^+$ $CD25^+$ Tregs.[80,81]

$CD8^+$ T cells[78] and generation of effective CD8 memory cells in turn requires CD4 T-cell help.[82-84] This help is provided through activation of DC via CD40L–CD40 interactions and the production of cytokines such as IL-2, although some studies have suggested that when cytotoxic T-lymphocyte precursor frequencies are high, priming of CD8 T cell responses may be CD4 T cell independent. In these cases though, memory generation is likely to be hampered because of the absence of IL-2 during priming,[85] and primed T cells may commit fratricide through expression of TRAIL,[86] or become functionally tolerant upon receiving signals through the inhibitory receptor PD-1.[87]

Evidence is accumulating that pDCs, which were believed to play a role only in the innate immune response because of their ability to produce high levels of IFN type I, can present viral and tumor antigens to initiate both $CD4^+$ and $CD8^+$ T-cell responses.[88,89] Plasmacytoid DCs mature in response to certain viral infections (e.g., influenza and HIV), thereby providing an important link between innate and adaptive arms of the immune response. Similar to their myeloid counterparts, however, pDCs display plasticity, even inducing immunosuppressive responses depending on their microenvironment or the stimuli to which they are exposed.[90] Genetic depletion of pDCs, using transgenic mice expressing diphtheria toxin receptor under the control of BDCA-2 promoter, has allowed dissecting precisely the role of pDC in antiviral responses. In the case of vesicular stomatitis virus infection, depletion of pDCs resulted in decreased specific $CD8^+$ T-cell responses, but depletion of pDCs during lymphocytic choriomeningitis virus (LCMV) did not affect the magnitude of LCMV-specific $CD8^+$ T-cell response. This suggests that pDC may be required to enhance weak cytotoxic T-cell responses.[91] A recent study targeting Siglec-H by conditional genetic ablation specifically induced specific pDC depletion and demonstrated a complex role of pDC. Siglec-H and pDC depleted pDC suppressed antigen-specific $CD4^+$ T-cell responses in vivo, but they were required to enhance $CD8^+$ T-cell response to soluble and microbial antigens.[92]

B-CELL ACTIVATION

In addition to affecting T-cell function, DCs can also influence B-cell proliferation, isotype switching, and plasma cell differentiation.[93] DC produce factors that activate and induce B-cell proliferation (B-Lys and APRIL).[94] Furthermore, DCs stimulate antibody responses in a T–cell–independent manner against polysaccharide antigens. The initial interactions between B cells and DCs occur in the T-cell area of lymph nodes and in the germinal centers of lymph nodes or splenic red pulp (or both). Importantly, antigen-exposed cDCs possess a specialized nondegradative pathway, which allows them to present internalized antigens in their native state for the engagement of B-cell receptors (BCRs) on B cells. This is mediated by endocytosis of antigenic immune complexes through the inhibitory Fc receptor FcγRIIB and recycling of the endocytic vesicle to the surface without antigen degradation.[95] The follicular DCs, which are present in germinal centers of lymph nodes and which constitute a different class of DCs, participate in the maintenance of B-cell memory by formation of multiple antigen–antibody complexes and continuous stimulation of B cells. The antigen–antibody complexes may remain in the lymph node for an extended period of time (up to months or years).

NATURAL KILLER CELL ACTIVATION

The interactions between DCs and NK cells are complex and further underscore a role of DCs as a link between innate and adaptive immunity.[8] Direct interactions between NK cells and mature DCs can result in NK cell activation as well as the potentiation of their cytolytic activity, and conversely, NK cells can induce further DC maturation. NK cells and DCs can form an immune synapse, probably helping directional and confined secretion of cytokines as well as facilitating receptor–ligand interactions on one another. Activated NK cells induce DCs through both cell contact (involving NKp30) and TNF-α and IFN-γ secretion. In turn, activated DCs secrete IL-12/IL-18, IL-15, and IFN-α/β, which enhance IFN-γ secretion, proliferation, and cytotoxicity of NK cells. In some conditions, NK cells can lyse DCs through NKp30, although mature DCs are protected from cytolysis. This might represent a form of "cellular editing" whereby immature and tolerogenic DCs are cleared by NK cells in the course of an ongoing immune response.[96]

It is thus possible that DC and NK cells play complementary roles in sensing pathogens such that DCs could be the first to detect microbes through their expression of PRR (TLR, NOD proteins), whereas NK may get activated in the absence of overt inflammation but in the presence of ligands for activating NK-cell receptors, such as in the settings of tumors (which frequently lose MHC class I expression or express NKG2D ligands, such as MIC-A/B). In both situations, either DCs or NK cells could create an inflammatory environment and induce the integrated activation of other cell types. Thus, in mice, infection by murine cytomegalovirus (CMV) induces pDCs to secrete high levels of IFN-α/β, bit $CD8\alpha^+$ DC are the major producers of IL-12, and resistance to the virus is associated with expansion of $Ly49H^+$ NK cells, driven by IL-12/IL-18.

The interaction between NK cells and DC is likely to take place early during the course of an immune response. This allows DC to exploit the ability of NK cells to kill tumor or virus- or parasite-infected cells and to cross-present this material to T cells.[97]

ACTIVATION OF OTHER ELEMENTS OF THE IMMUNE SYSTEM

Dendritic cells have proven to be quite versatile in their ability to interact with many constituents of the immune system. For example, they can activate NK T cells by presentation of the synthetic ligand α-galactosyl ceramide on CD1, inducing the production of cytokines such as IFN-γ and resistance to tumors.[98] CD1 restricted γ δ T cells, which respond to microbial antigens from *Mycobacterium tuberculosis*

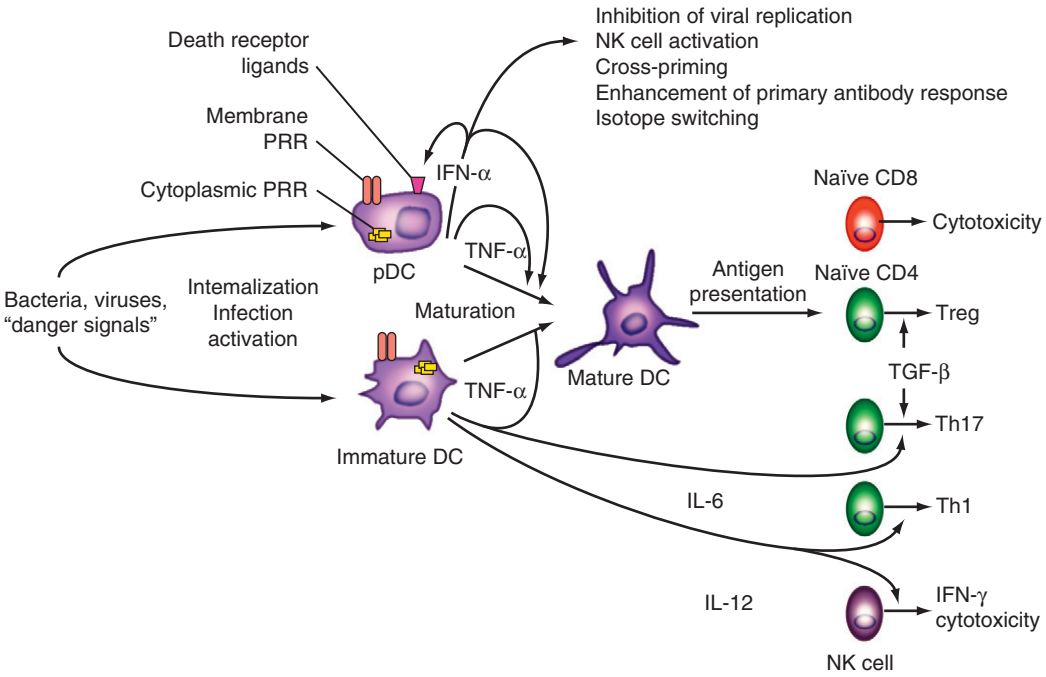

Figure 21-3 DENDRITIC CELLS (DCs) LINK INNATE AND ADAPTIVE IMMUNITY. Through the expression of pattern-recognition receptors (PRRs), such as Toll-like receptors, DCs act as sensors of pathogen intrusion. Upon signaling by PRRs, DCs secrete cytokines and express receptors allowing stimulation of the innate immune system. Interferon-α (IFN-α) or interleukin-12 (IL-12) stimulate natural killer (NK) cell activation while also inducing the expression of death-receptor ligands (TRAIL) on DCs, harnessing them for direct killing of infected cells. They take up antigens through direct infection or phagocytosis, undergo a complex program of maturation by upregulating the expression of costimulatory and major histocompatibility complex (MHC) molecules, migrate to the secondary lymphoid organs, and stimulate naïve T cells. They secrete cytokines, skewing the type of response induced toward Th1, Th2, regulatory T cell (Treg), or Th17 differentiation, inducing the generation of cytotoxic CD8 T cells, or participating in the generation of antibody responses. *pDC,* Plasmacytoid dendritic cell; *TGF,* transforming growth factor.

and other organisms, induce maturation of resting DC, and induce IL-12 production. This pathway and the IFN-γ secretion by activated γδ T cells, provide the immune system with a source of activated APCs, which can polarize Th1 responses.[99]

In summary, the influence of DCs on other cell types of the immune system is broad and integrative (Fig. 21-3). Future studies will ascertain the interplay between the myriad of host cells and the innate and adaptive immune response.

TOLERANCE AND AUTOIMMUNITY

Dendritic cells play a pivotal role in the balance between immunity and tolerance. DCs are important in the induction of both central and peripheral tolerance. In the former, DCs play a role in deletion of autoreactive T cells in the thymus. In the latter, imDCs in their steady state induce T-cell deletion, anergy, or generation of regulatory T cells, which interfere with IL-2 production and proliferation of effector T cells against self.[100] Regulatory T cells are $CD4^+$ or $CD8^+$ in nature and express CD25, CTLA-4, and the transcription factor Foxp3 (a member of the forkhead transcription factor family). These cells exert their tolerogenic effects either via cell contact or through release of immunosuppressive cytokines such as IL-10[101] or TGF-β, preventing proliferation and cytotoxicity of activated CD4 or CD8 T cells, and can also inhibit TLR-mediated maturation of cDCs but not pDCs.[102] It was recently suggested that a subset of human thymic DCs, upon activation by TSLP from epithelial cells of Hassall corpuscles, positively selects $CD4^+$ Tregs in the thymic medulla, thereby playing a central role in the generation of naturally occurring Tregs.[103] How might DC in peripheral tissues induce tolerance is an open question. One report suggests that uptake of antigens via receptors such as DEC-205, a member of the C-type lectin family, can induce T-cell deletion or generation of antigen-specific Tregs.[104]

Dendritic cells may also be actively rendered tolerogenic via a number of mechanisms. Resting imDCs acquire self-antigens through phagocytosis of apoptotic bodies formed as a consequence of physiologic cell turnover. In the absence of a maturation signal, these DCs induce tolerance to such self-antigens.[105] Some studies have suggested that ligation of specific receptors on DCs such as complement receptors CR3 and CR4[106] by apoptotic cells inhibit their maturation,[106] thereby ensuring the delivery of a tolerogenic rather than stimulatory signal. Others include MER, CD91/calreticulin, and CD36/αvβ5. External factors such as steroids, IL-10, and TGF-β may also compromise DC immunostimulatory function by inhibiting their full maturation.[107] For example, DCs isolated from tumor environments are poorly immunostimulatory because of the presence of immunosuppressive cytokines or the induction of costimulatory molecules such as PDL-1, which deliver negative signals.[108] Moreover, there may exist distinct tolerogenic DC subsets. A particular DC subset was identified in normal mice that were CD11c-low/CD45RB high), secreted IL-10 after activation, and induced tolerance through induction of Tregs.[109] Recently in mice, pDCs have been shown to induce tolerance against a vascularized cardiac allograft upon administration of a tolerizing regimen.[110] After capturing pDC alloantigens from the graft, they migrated to peripheral lymph nodes and induced specific Tregs.[110] Human DC deficiencies are associated with a loss of Tregs, and it seems that DC and Treg reciprocally control each other's expansion, where DCs control Treg expansion and Tregs control DC numbers through a Flt3-dependent feedback loop.

Recently, production of indoleamine 2,3-dioxygenase (IDO) has been proposed to account for some of the tolerogenic potential of DC.[111] IDO is an enzyme that degrades the indole moiety of tryptophan and other molecules and induces the production of immunoregulatory metabolites known as kynurenines. Local depletion of tryptophan and increase in proapoptotic kynurenines affects T-cell proliferation and survival. Induction of IDO in DCs has been postulated as one means by which deletional tolerance occurs. This is compounded by the observation that Tregs may directly act on DCs via CTLA-4-B7 interactions to promote IDO production.[111] Also, pDCs activated through TLR7 or TLR9 upregulate the expression of IDO and can induce the generation of Tregs from naïve $CD4^+$ T cells. Moreover, expression of death-inducing ligands such as FasL may render DCs capable of killing activated T cells.[104,112] Altogether, these properties of DCs make them attractive candidates for inducing tolerance in the setting of transplantation or autoimmunity. Indeed, injection of antigen pulsed immature DCs in vivo induces antigen specific IL-10–producing $CD8^+$ Tregs, which supplant their IFN-γ–producing effector cell counterparts.[78,113]

Dendritic cells are also believed to be important for the induction of the chronic phase of autoimmune diseases. IFN-α produced by pDCs is thought to contribute to the autoimmune response in SLE.[114,115] Plasmacytoid DC can be activated through TLR7 and 9 by immune complexes containing RNA and DNA, respectively, from dead cells and induced to secrete high amounts of IFN-α. This can further promote the differentiation of monocytes into activated cDCs, thus enhancing presentation of self-antigens, increasing the cytotoxicity of CD8 and NK cells, and promoting plasma cell differentiation and subsequent generation of pathogenic autoantibodies. Several host factors can convert self DNA into triggers of pDC activation. For example, the antimicrobial peptide LL-37 forms large aggregates with self-DNA released from dying cells, protecting it from extracellular nuclease digestion, and is taken in pDCs for induction of type I INF. LL-37 has been found to be overexpressed in psoriatic skin, and the gene encoding LL-37 is the most upregulated in the blood of lupus patients.[116]

A role of cDCs during disease onset is also strongly suggested in arthritis, multiple sclerosis, diabetes, and atherosclerosis.[117-119] The similarity between outcomes of microbial infection and autoimmunity suggests that TLRs or PRRs triggered by microbial molecules on DCs induce their maturation and secretion of cytokines and chemokines. This may cause DCs to upregulate presentation of self-antigens in such instances as apoptosis or necrosis induced directly by pathogens or antimicrobial immune response. Endogenous ligands such as extracellular matrix breakdown products (heparan sulfate and hyaluronate), molecules released from necrotic cells (high-mobility group box 1 protein [HMGB1], uric acid, or even endogenous nucleic acids), fibronectin and heat-shock proteins, which can activate TLRs on cDCs, may also contribute to the generation of autoimmune responses.[120]

SUBVERSION OF DENDRITIC CELL FUNCTION BY PATHOGENS AND TUMORS

Several pathogens have evolved different mechanisms to inhibit DC functions, allowing them to downregulate specific immune responses and hence persist in the host. Numerous viruses, such as measles, vaccinia, herpes simplex, smallpox, and lymphocytic choriomeningitis virus, can impair antigen presentation by infected cells through different mechanisms. Thus, human CMV induces downmodulation of MHC class I or class II molecules and can inhibit activated T cells through secretion of a virally encoded IL-10 homolog. Directly targeting DCs allows viruses to impair the generation and quality of the antiviral immune responses. In mice, murine CMV has been shown to trigger paralysis of infected DCs, preventing them from secreting IL-12 or IL-2 upon TLR4 triggering, impairing their capacity to mature, eventually rendering them unable to prime an effective T cell response.[121] Some viral products interfere with IFN-α secretion pathways, such as the E6 oncoprotein of human papillomavirus, inhibiting transactivation of IRF3 or IRF7, or NS3/4A inhibiting RIG-I and MDA5-mediated activation of IRF3.

It is now well documented that in HIV-infected patients that not only the number of pDCs and cDCs in blood is reduced, but cDCs are also less efficient at stimulating primary T-cell responses and may generate IL-10–secreting T cells with a potential regulatory role. DCs may be the first cells to encounter HIV in mucosal tissues and may mediate the spread of virus to $CD4^+$ T cells in lymphoid organs. Formation of virions and release from the cell surface is counteracted by tetherin, an interferon-regulated restriction factor, that retains virions at the cell surface. The Vpu accessory protein antagonizes tetherin activity to allow virion release. cDCs can mediate transinfection of $CD4^+$ T cells through the formation of an infectious synapse, carrying the virus with or without infection of the DCs themselves. DCs express the coreceptors CD4, CCR5, CXCR4, and the C-type lectin DC-SIGN necessary for binding or entry of HIV, albeit at lower levels than CD4+ T cells, although the expression of DC-SIGN remains to be firmly demonstrated. HIV can infect DCs, but its replication is not as efficient as in $CD4^+$ T cells because of expression of the viral restriction factor SAMHD1, a deoxynucleoside triphosphate triphosphohydrolase. The viral envelope protein gp120 can bind to CD4 and C-type lectins such as DC-SIGN and mannose receptor, but the contribution of each receptor to binding and internalization may vary depending on the particular type of DC encountered by HIV. Thus, although DCs are not the main reservoir of HIV, the virus can "highjack" DCs to mediate its spread to $CD4^+$ T cells from mucosal tissues to lymphoid organs. Nevertheless, although cDCs only get minimally activated by HIV, pDCs can get infected and be strongly activated by HIV, causing them to secrete high amounts of IFN-α and other antiviral molecules. This can inhibit the replication of HIV in $CD4^+$ T cells, suggesting that the two subsets play different and opposing roles during HIV infection. However, pDCs may also function to downregulate the response by secreting TRAIL.[122,123] Furthermore, the continuous secretion of IFN-α by pDCs stimulated by HIV may be detrimental to the host by participating to chronic immune activation and $CD4^+$ T-cell depletion.

Tumors also evolve mechanisms to negate the functionality of DCs. For example, the number of cDCs (but not pDCs) is reduced in blood of cancer patients, and these numbers of DCs are restored upon surgical removal of the tumor, indicating a systemic defect orchestrated by the tumor cells. Moreover, increased numbers of imDCs are found in blood and tumor tissue, also displaying an impaired response to activation stimuli. A subset of immature myeloid cells, composed of immature macrophages, DCs, granulocytes, and myeloid cells at early stages of differentiation, accumulate in the secondary lymphoid organs and tumors of tumor-bearing mice and presumably humans. These myeloid suppressor cells are endowed with suppressive activity toward antitumor T cells through various mechanisms such as regulation of arginine metabolism and release of ROS. In some tumors, IDO-expressing pDCs are found in significant numbers, thereby decreasing availability of tryptophan and generating tryptophan catabolites. IDO expressing pDCs can activate intratumor Tregs. It seems that tumors impair early myeloid, and in particular DC, differentiation at a systemic level by secreting soluble factors such as VEGF, M-CSF (macrophage colony-stimulating factor), IL-6, IL-10. Many tumors constitutively express activated STAT3, a transcription factor partially implicated in the production of these cytokines, the constitutive activation of which also impairs the secretion of proinflammatory cytokines. STAT3 (signal transducer and activator of transcription 3) is also responsible for abnormal differentiation of hematopoietic precursor cells, suggesting that inhibition of its activity may be a promising route toward restoring DC function in cancer. The tumor microenvironment thus profoundly impact on the function of infiltrating DCs and T cells, and it has recently been shown that overexpression of matrix metalloproteinase-2 (MMP-2) conditions DCs to produce low levels of IL-12 and to express OX40-L, which biases anti-tumor CD4+ T cells toward a suboptimal Th2 differentiation.[124]

IMMUNOTHERAPEUTIC STRATEGIES AND CLINICAL TRIALS

The past decade has seen an increasing interest in clinical applications of DCs, harnessing the growing knowledge about DC biology. It is becoming apparent that any effective vaccine must activate and induce antigen presentation by DCs, the most potent cells at stimulating T-cell immunity. A number of clinical trials (mostly phase I and II) have been completed describing the use of DCs in cancer immunotherapy (e.g., non-Hodgkin lymphoma, malignant melanoma, multiple myeloma, prostate cancer, renal cell carcinoma, breast cancer) and in the immunotherapy of human pathogens such as HIV. Most of these studies have relied on monocyte-derived DCs, but a few have used DCs prepared from $CD34^+$ HPC. A critical issue is the antigen delivery to the DCs, with the nature of the antigen and the vehicle for delivery probably being decisive. DCs can be pulsed with defined antigens in the form of HLA-binding antigenic peptides or whole proteins or the whole assortment of tumor antigens upon phagocytosis of dying or opsonized autologous tumor cells. Artificial fusion of DCs with tumor cells allows the generation of hybrid cells with characteristic of DCs but expressing the whole set of tumor antigens as well. Because autologous tumor cells are not always available from patients with advanced disease, allogeneic tumor cells of the same histologic origin expressing shared tumor antigens are also used for loading DCs.

Dendritic cells themselves can also be genetically modified through transfection. However, DCs are terminally differentiated nondividing cells and difficult to transfect. Methods using RNA electroporation and infection by recombinant viruses (lentivirus, poxvirus, herpes virus, and adeno-associated virus) lead to foreign transgene expression in DC. Another strategy is to target DC in situ using antibodies recognizing DC-specific molecules, such as DEC-205, as demonstrated in mouse models.[125] Recently a phase II trial involved priming by a recombinant vaccinia virus encoding prostate-specific antigen and the "tricam" CD80, ICAM-1, and LFA-3, and boosting by a fowlpox virus. GM-CSF was injected at the same time to further amplify immune stimulation. This vaccine was designed to mimic antigen presentation by DCs, even in an incomplete way, and induce significant overall survival benefit.[126]

Because the activation state of antigen-presenting DCs is a determining factor in shaping the ensuing immune response, genetic engineering of DCs or triggering activating receptors also allows enhancing their secretion, migration, and antigen presentation capacity. Thus, DCs can be activated by artificial TLR ligands (e.g., R848, which is a ligand for TLR7; unmethylated CpG oligonucleotides, which are ligands for TLR9; or inflammatory cytokines, such as IL-1β, IL-6, or TNF-α) that can be used in a clinical setting to activate DCs before injection or even in vivo.[127] DCs can also be transfected for immunostimulatory molecules, such as cytokine genes (e.g., IL-2, IL-12), or inhibitory siRNA for molecules dampening DC activation (e.g., SOCS1).

Anticancer vaccination can be used in synergy with chemotherapy and radiotherapy. The rationale is that chemotherapy and radiotherapy triggers tumor cell death, which provides a source of tumor antigens to DCs while at the same time inducing exposure of immunogenic molecules on tumor cells. Thus, anthracycline-treated tumor cells expose the ER chaperones calreticulin (CRT) and ERp57 because of induction of an ER stress response and potentiate dying tumor cells phagocytosis. Death of tumor cells is also accompanied by release of non histone chromatin binding nuclear protein HMGB1, which can trigger TLR4, and ATP, which upon binding to P2RX7 potentiates inflammasome activation and IL-1β release. Increased uptake of tumor antigen in the context of maturion signals strongly enhances cross-presentation and cross-priming of tumor antigens by DCs.

Recent successes in DC vaccination trials have been witnessed using intratumoral injection of the CpG oligonucleotide (PF-3512676) in low-grade B-cell lymphoma, thus targeting TLR9 on pDCs and B cells. Complete and partial clinical responses were observed in several patients with induction of tumor-specific CD8 T cells responses.[128,129] Tumor regressions were observed in injected and distant tumor sites. Another phase III clinical trial in metastatic prostate cancer, consisting of enriched blood APCs pulsed with a fusion of prostatic acid phosphatase with GM-CSF, led to about 4 months of prolonged median survival. This vaccine (sipuleucel-T [APC8015]) has recently been approved by the Food and Drug Administration for treatment of metastatic prostate cancer. A phase III trial in metastatic melanoma using peptide vaccination with high-dose IL-2 showed a significantly increased overall response rate and progression-free survival. Another phase III trial in patients with follicular lymphoma using idiotype vaccination increased the duration of chemotherapy-induced remission. Although the target APCs in these vaccines has not been defined yet, they most likely involved DCs to induce or expand antitumor immune responses.

It is likely that to achieve significant clinical responses upon vaccination for cancer, combining DC vaccination with other strategies will improve the therapeutic outcome. For example, some strategies aim at depleting or inactivating Tregs (using a toxin targeting CD25, a molecule expressed by Tregs, or cyclophosphamide), alleviating T-cell anergy (using antagonistic CTLA-4 or PD-1), differentiating myeloid suppressor cells into nonimmunosuppressive cells (by injection of retinoic acid derivative ATRA [all-trans-retinoic acid]), common γ chain cytokines such as IL-7, which have potent effects on T-cell survival and function, or adoptive immunotherapy of in vitro activated T cells.[130,131] Finally, it seems that irradiation of the tumor tissue conditions it for enhanced migration of APCs and T cells, augments MHC class I expression on tumor cells, and induces apoptotic cells death, thus augmenting delivery of tumor antigens to DCs.[132-134] The identification of specific surface receptors regulating DC–T-cell interaction and T-cell activation and differentiation allowed using targeting antibodies functioning as immune modulators. Thus, agonistic antibodies targeting GITR, OX40, CD137, or CD40 or cytokines potently enhancing cytotoxic T-cell responses, such as IL-15, can be harnessed to enhance vaccine-induced antitumor immune responses.

Thus far, DC vaccines have not met the desired endpoints in clinical studies (i.e., tumor regression) in the majority of patients despite clear evidence that DC vaccination can induce measurable cellular or humoral immune responses in cancer patients.[135-138] In a recent phase III trial, vaccination of stage IV melanoma patients by DCs loaded with multiple peptides could not be demonstrated to be more effective than the standard chemotherapy treatment.[139] However, the optimal DC type, optimal maturation signal(s), mechanism of antigen delivery, nature of antigen, frequency of immunization, and route of administration still remain to be determined. Furthermore, it may be that only a subset of patients may be able to respond to DC vaccination, or in the case of advanced stage cancer patients, to any vaccination. In the authors' opinion, DC immunotherapy will be most efficacious when coadministered with an adjuvant and when the tumor burden is low. The timing of vaccination is probably also crucial, and frequent immunizations may dramatically improve the clinical efficacy.[140] In the setting of HIV infection, a recent study in a small group of chronically infected individuals showed that vaccination with DCs loaded with chemically inactivated virus allows stabilization and even suppression of viral load for an extended period of time without any other treatment.[141] Vaccination with DCs holds great promise in cancer and infectious diseases, but its potential is likely to be best exploited in combination with other strategies manipulating other arms of the immune system.

Although DCs are considered the most potent cells in inducing T-cell responses, they can also function as tolerizing cells, a function that can be harnessed against autoimmune diseases and in a transplantation setting. Thus, it is possible to differentiate in vitro maturation-resistant imDCs or differentially activated DCs using biologic agents such as IL-10, TGF-β, or the fusion protein CTLA-4-Ig, and pharmacologic agents such as corticosteroids, cyclosporine, rapamycin, mycophenolate mofetil, vitamin D3, or prostaglandin E_2. The clinical relevance of some of these strategies is being evaluated. Another way to dampen pathologic immune responses is to use antagonists for TLRs or other innate immune sensor participating in

amplifying damaging responses. Thus, because the role of DNA-immune complexes has been established as important in the etiology of SLE, synthetic inhibitory oligodeoxyribonucleotides have been developed that can prevent or inhibit activation through TLR9 on pDCs and B cells and block SLE in animal models. Finally, significant challenges remain with respect to DCs based immunotherapy ranging from applicability of preclinical models to humans to regulatory and funding hurdles.

FUTURE DIRECTIONS

Dendritic cells are a sparsely distributed population of BM derived mononuclear cells that exist in an immature form in virtually all tissues in the body. DCs serve as professional APCs with extraordinary capacity to stimulate naïve T lymphocytes (as well as B cells, NK cells, and NK T cells) and initiate primary immune response. They link innate and adaptive immunity and are responsible for activation and inhibition of effector cells. Their clinical applications in cancer, transplantation, and chronic virus infections are under investigation.

CHAPTER 22

COMPLEMENT AND IMMUNOGLOBULIN BIOLOGY

David E. Isenman, Robert Mandle, and Michael C. Carroll

This chapter is divided into two parts. The first part details the current understanding of the activation and biology of the complement system and how it links innate and adaptive immunity. The second part focuses on immunoglobulins and their importance in protecting against disease. The goal of this chapter is to impart to the reader the underlying role of the complement system and antibody in protecting the host from microbial insult and disease.

THE COMPLEMENT SYSTEM: AN OVERVIEW

Complement refers to a family of distinct proteins that play a pivotal role in host defense against infection. In the 1880s, the serum factors involved in host response to pathogens were placed into two categories based on sensitivity to heat. Whereas the heat-stable component, antibody, was recognized as being specific for the invading pathogen and arose after immunization, the heat-labile (>56° C [133° F]) fraction displayed nonspecific killing activity. The heat-labile fraction acted to complement the antibody-mediated lytic killing of targeted organisms.[1-3]

In addition to its lytic role in the effector arm of the antibody response, the complement system serves several other functions. First, components of the complement system are involved in clearance of targeted microorganisms by the process of opsonization. *Opsonization* is the coating of a particle with proteins that facilitate phagocytosis of the particle by tissue macrophages and activated follicular dendritic cells (FDCs) as well as binding by receptors on peripheral blood cells.[4,5] Second, complement promotes inflammation by releasing small peptide fragments from complement proteins. These peptides cause mast cell degranulation, smooth muscle contraction, and directed migration (chemotaxis) of motile cells to sites of inflammation.[6,7]

Complement can be activated via three distinct pathways: classical, lectin, and alternative. Although all depend on different molecules for their initiation, eventually they converge to generate the same set of effector molecules. Each of these pathways is described here (Fig. 22-1).

Classical Pathway

The classical pathway (CP), so called because it was the earliest studied arm of the complement system, directly links the innate and acquired immune systems. There are nine proteins in the CP. As a matter of terminology, each CP component protein is designated with an uppercase C followed by a number. Fragments of these proteins generated by cleavage during the complement cascade are designated with a lower case letter suffix (e.g., C3a, C3b). In general, the smaller product arising from a proteolytic activation step is given the fragment designation "a," and the larger product is designated "b." The sole exception to this rule is for the naming of the C2 proteolytic activation fragments, where, for historical reasons, the larger fragment is C2a and the smaller one is C2b.

C1, the first component of the CP, binds and is activated by the Fc portion of the antibody molecule. C1q is a macromolecule complex composed of three individual protein subunits: C1q, C1r, and C1s.[8-12] The largest of these subunits, C1q, is an 18-chain molecule with six copies each of three chains: A, B, and C. Structurally, C1q consists of a central core with six radiating arms. Each arm possesses a triple helical structure similar to collagen that is capped at the end with a head region consisting of a quaternary assembly of the globular domains from each of chains A, B, and C. C1q, largely through ionic interactions, links the C1 complex to the antibody molecule. In addition to its capacity for binding to antibody molecules, C1q possesses the capability to bind directly to the surfaces of some microorganisms and apoptotic cells, not unlike mannan-binding lectin (MBL; see lectin pathway discussion, later).

Associated with C1q are two molecules each of C1r and C1s. In unactivated C1, C1r and C1s are proenzyme serine esterases. Upon binding of C1q with an array of target-associated immunoglobulin G (IgG) Fc regions, or directly to surface molecules of the pathogen, a conformational change occurs that leads to reciprocal autoactivation of the associated C1r molecules. The active form of C1r then cleaves its associated C1s to generate an active serine protease.

Activated C1s is responsible for cleaving C4 and C2, the next two proteins in the complement pathway. Cleavage of C4 yields two fragments: C4a and C4b. C4b possesses a highly reactive thioester group that allows it to bind covalently to molecules in the immediate vicinity of its active site. Only a small proportion of the C4b produced binds to proteins or carbohydrates on the targeted surface; the rest is inactivated by reaction with water in the surrounding milieu. This helps to prevent inadvertent C4b binding to surrounding host cells.

C2, the next substrate in the CP cascade, is susceptible to cleavage by C1s. Upon association with C4b, C2 is cleaved by activated C1s into two fragments: C2a and C2b. C2a, which is now an active serine protease, remains bound to C4b, thereby confining it to the targeted surface. C4b2a is termed the *C3 convertase,* an enzymatic complex that is responsible for binding and cleaving C3, the next component in the cascade. The function of the C3 convertase is to cleave large numbers of C3 molecules to produce C3b and C3a. Nascently activated C3b, similar to C4b, also possesses a highly reactive thioester bond, allowing a portion of the nascent C3b to covalently bind to the targeted surface (opsonization of the target) and thereby mark it for phagocytosis. The activated thioester in the bulk of the nascent C3b becomes water hydrolysed and can no longer bind to a target. By contrast, all of the C3a fragment remains in solution, where it initiates a local inflammatory response.

An Ig-independent mechanism for activation of C1q has been identified.[13] The lectin protein Sign R1, which is expressed on a subset of macrophages within the outer marginal zone sinus of the spleen, is capable of capturing to the surface of the marginal zone macrophage both C-polysaccharide–containing bacteria and C1q. The recruited C1 becomes activated and propagates the CP to deposit C3b on the captured bacterium. Recently, Sign R1 was identified on the surface of resident dendritic cells (DC) in draining lymph nodes and shown to be important in capture and transport of inactivated influenza virus.[14] This novel pathway provides an alternative innate recognition of pathogens leading to activation of the CP of complement.

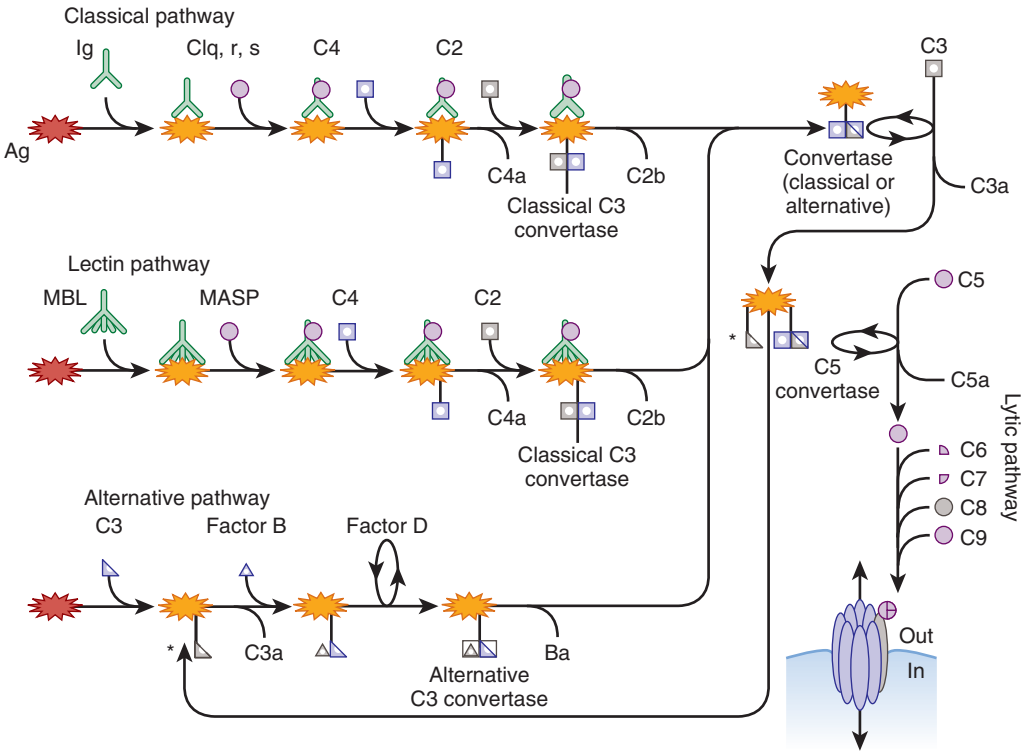

Figure 22-1 SCHEMATIC OVERVIEW OF THE COMPLEMENT CASCADE. Classical, lectin, and alternative pathways commence from the left side of the figure, leading to the converging point of C3 activation *(top right)*. In every subsequent proteolytic step, the position of the new addition to the antigen complex is shown in *black* for clarity. From the central C3 activation step downward, the C3 amplification loop through the alternative pathway is indicated by *asterisks*. The lytic pathway is initiated with the formation of C5 convertase and leads to the assembly of the C5–C6–C7–C8–C9 membrane attack complex, which interferes with the target's structural integrity by penetrating the cellular membrane *(bottom right)*. *MASP,* mannan-binding lectin–associated serine protease; *MBL,* mannan-binding lectin.

Lectin Pathway

Before continuing with the discussion of the complement cascade at the point of C3 cleavage by convertase, we turn our attention to the other two complement-activating pathways: the lectin pathway (LP) and the alternative pathway (AP). What will become evident is that all of these pathways converge at C3.

The lectin pathway is a relatively recently described pathway for complement activation.[15,16] Mannan-binding lectin (MBL), similar to C1q, is a triple helical structure with collagen-like arms (most commonly four) coupled to globular domains, which form carbohydrate recognition domains that bind repeating polysaccharides present on the surfaces of many microorganisms. MBL attaches to the terminus of polymeric carbohydrate chains in the following order: mannose > GlcNAc > fucose > glucose. The greatest avidity appears to be for repeating mannose-based structural patterns typical of microbial surfaces. On vertebrate cells, these sugars are not as dense as on microbial surfaces, thus decreasing the avidity of the MBL-binding interaction, and furthermore, they often are covered by sialic acid residues, thus limiting recognition by MBL. Upon binding to polysaccharides on a pathogen surface, MBL activates the serine proteases MBL-associated serine protease (MASP)-1 and MASP-2. MASP-2 acts similar to C1s, cleaving C4 and C2 and thereby forming a C3 convertase, C4b2a, as found in the CP.[17] The role of MASP-1 in the LP is less well defined. Because it cleaves C2, but not C4, its role may be more augmentory than essential. Along similar lines, although complexes consisting of MBL and only MASP-2 are activatable, the availability of MASP-1, in a yet to be clarified manner, augments the activation process.[14]

Mannan-binding lectin serum concentration can differ by up to 1000-fold among individuals, with those having low circulating MBL apparently more vulnerable to infections. MBL insufficiency appears to be a particular risk factor for infections in infants and individuals undergoing chemotherapy or immunosuppression treatment.[18]

Given the relatively recent discovery of the MBL pathway in the 1990s, progress into fully understanding this pathway is now just beginning. Gene-targeted knock-out mouse models deficient in MBL components have been described. Generally, in pathogenic microbe infection models, such as *Candida albicans* or *Staphylococcus aureus,* MBL knock-out mice showed increased susceptibility to systemic infection and relatively much higher mortality compared to wild type.[19,20]

Alternative Pathway

The AP may represent one of the earliest forms of innate immunity. Unlike the CP or LP pathway, the AP can be fully activated in the absence of specific pathogen binding by a "recognition" equivalent to C1q or MBL.[21] In fact, the AP is always "on" at a low level. In addition, the AP forms and uses the distinct C3 convertase C3bBb.[22]

Complement C3 is a two-chain protein with an apparent molecular weight of approximately 200 kDa. The crystal structure of native C3, shown as a domain-colored ribbon model in Fig. 22-2, *A,* identified 13 distinct domains, including the thioester domain (TED), which contained the covalent binding site.[23] In the native molecule, the intramolecular thioester bond, formed between the side chains of cysteine and glutamine residues within the sequence CGEQ, is buried within a hydrophobic interface formed between the TED and MG8 domains, which is nevertheless close to the protein's

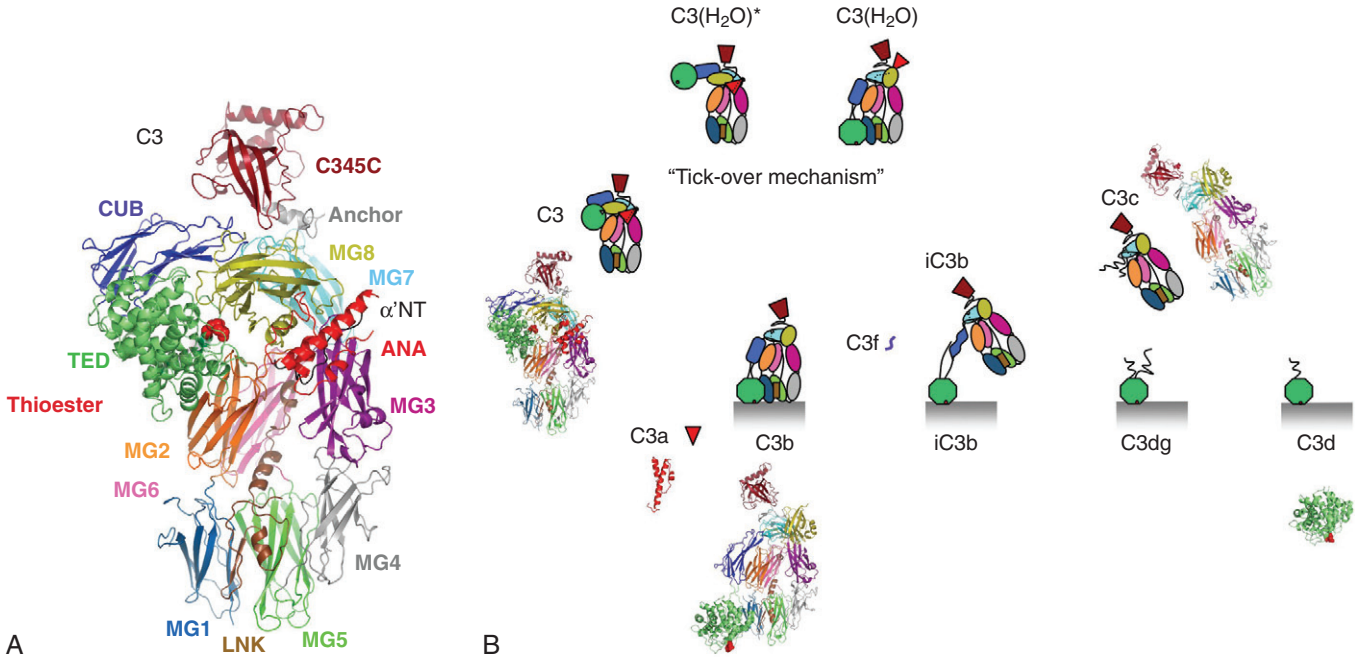

Figure 22-2 THE STRUCTURE OF NATIVE C3, ITS CONFORMATIONAL INTERMEDIATES, AND ITS CLEAVAGE FRAGMENTS. **A,** Ribbon diagram representation of the x-ray crystal structure of native C3 indicating the 13 domains (*bold lettering,* color-coded the same as the domain) of which it is composed. **B,** Structure-based cartoon representation of the conformational states of intact C3, as well as its cleavage fragments. Where these cartoons are derived from x-ray structures, those structures are depicted as ribbon diagrams adjacent to the cartoon. The remaining cartoons are based on electron micrograph images,[199] as well as established biochemical data. In all cases, the domain colors in the cartoons correspond to those in the ribbon diagrams. Proteolytic activation of C3 to C3b results in an approximate 90-Å downward movement of the thioester domain (TED), a significant repositioning of the CUB (complement C1r/C1s, urchin EGF, bone morphogenic protein 1), and a flipping of the positions macroglobulin 7 (MG7) and MG8 domains. The reorientation of these domains creates binding sites for ligands of C3b that were not present in the native molecule. The reactive thioester produced during this conformational transition is capable of binding a portion of the C3b molecules covalently to a target surface *(grey-shaded boxes)*. Subsequent cleavage of C3b by factor I releases a small C3f fragment and results in a reorientaction of the C3c portion of the molecule relative to C3d/TED within iC3b, a molecule that remains bound to the target. This reorientation relative to C3b relieves the steric blockage by MG1 of a portion of the binding site for CR2/CD21, as iC3b is an equivalent ligand to C3dg and C3d with respect to CR2 binding. C3dg and C3c are the products of an additional cleavage by factor I within the CUB domain. A noncomplement protease removes an N-terminal segment from C3dg, yielding the still target-associated C3d fragment. The remaining "squiggle" on C3d represents 16 residues at its C-terminus that are sufficiently flexible that they were not visible in the x-ray crystal structure of C3d. Although the thioester in native C3 is protected from the solvent, native C3 is in conformational equilibrium with a stable conformational intermediate, $C3(H_2O)^*$, in which the thioester become susceptible to hydrolysis. Although the equilibrium strongly favors the native state, if hydrolysis of the thioester in $C3(H_2O)^*$ occurs, it cannot reform, and the molecule undergoes a unidirectional conformational change to the $C3(H_2O)$ stage, which adopts both a C3b-like conformation and functional profile. This conformational transition of intact C3 is the basis of the "tick-over mechanism" for alternative pathway initiation. *(Modified from P. Gros, Utrecht University; contains elements previously published in Gros P, Milder FJ, Janssen BJ: Complement driven by conformational changes.* Nat Rev Immunol *8:48, 2008.)*

surface. The subsequent determination of the atomic structure of the activated form of C3 (i.e., C3b) demonstrated a dramatic shift in the location of the TED.[24,25] Proteolytic cleavage releases the C3a anaphylatoxin peptide, and the TED becomes fully exposed to engage potential targets (see structure-based cartoon depiction of C3b in Fig. 22-2, *B*). Thus, the dramatic shift in structure also exposes potential binding sites for factor B of the AP and competing sites for regulators of C3b, such as factor H (FH), membrane cofactor protein (MCP), complement receptor type 1 (CR1), and decay accelerating factor (DAF; all described later in this section). At a low so-called "tickover" level, the thioester bond undergoes spontaneous hydrolysis, forming $C3(H_2O)$. This conformationally altered C3b-like form of C3 (see Fig. 22-2, *B*) allows for binding to factor B, a plasma protein. Factor B is a serine protease that is approximately 30% identical to C2. The binding of factor B by $C3(H_2O)$ allows factor D, another protease, to cleave factor B to form Ba and Bb. Bb remains associated with $C3(H_2O)$ to form the $C3(H_2O)Bb$ complex. Factor D appears to function as a serine protease in its native state but can cleave factor B only when bound to C3. Recently, there has been an interesting connection found between factor D and MASP-1, a component of the LP. It was found that a *MASP-1/MASP-3* knockout mouse (the proteins MASP-1 and MASP-3 are alternative splice products of the same gene) completely lacked AP functionality. Upon further investigation, it was determined that the secreted factor D in this mouse possessed a five residue propeptide at its amino terminus. Removal of this propeptide from factor D by the addition of MASP-1 resulted in restoration of AP functionality.[26]

$C3(H_2O)Bb$ is an enzymatic complex capable of cleaving native C3. This complex is a fluid-phase C3 convertase. Although it is formed only in small amounts, it can cleave many molecules of C3. Much of the C3b produced in this process is inactivated by hydrolysis, but some attaches covalently to the surface of host cells or pathogens. C3b bound in this way is able to bind factor B, allowing its cleavage by factor D to yield Ba and Bb. The result is the formation of C3bBb, a C3 convertase akin to C4b2a found in the classical and MBL pathways, with the capability of initiating an amplification cascade.

In light of the nonspecific nature of C3b binding in the AP, it is not surprising that a number of complement regulators exist both in the plasma and on host cell membranes to prevent complement activation on self tissues. Some of these regulatory components are mentioned now for the sake of clarity; more detailed attention is provided later in this chapter (Table 22-1). CR1 and DAF (CD55) compete with factor B for binding to C3b on the cell surface and can

Table 22-1 Control Proteins of the Classical and Alternative Pathways

Name	Role in the Regulation of Complement Activation
C1 inhibitor (C1INH)	Binds to activated C1r, C1s, removing it from C1q
C4-binding protein (C4BP)	Binds C4b, displacing C2a; cofactor for C4b cleavage by factor I
Complement receptor 1 (CR1)	Binds C4b, displacing C2a, or C3b displacing Bb; cofactor for FI
Factor H (FH)	Binds C3b, displacing Bb; cofactor for factor I
Factor I (FI)	Serine protease that cleaves C3b and C4b: aided by factor H, MCP, C4BP, or CR1
Decay-accelerating factor	Membrane protein that displaces Bb from C3b and C2a from C4b
Membrane cofactor protein	Membrane protein that promotes C3b and C4b inactivation by factor I
CD59 widely	Prevents formation of membrane attack complex on autologous cells expressed on membranes

displace Bb from a convertase that has already formed.[27] Factor I (FI), a serum protease, in concert with CR1 or MCP (CD46) can prevent convertase formation by converting C3b into its inactive derivative, iC3b.[28] CR1 is unique among the FI cofactors in facilitating an additional proteolytic cleavage of iC3b to yield C3c and C3dg (see Fig. 22-2, *B*). Trimming of the latter by noncomplement proteases yields the proteolytic limit fragment C3d, which structurally corresponds to the TED domain (see Fig. 22-2, *B*). Another complement regulatory protein found in the plasma is FH. FH binds C3b and is able to compete with factor B and displace Bb from the convertase. In addition, FH acts as a cofactor for FI to convert C3b to iC3b. In addition to interaction sites for C3b, FH possesses two distinct binding sites for polyanionic molecules, particularly various sulphated glycosaminoglycans (e.g., heparan sulphate) or arrays of sialic acid (e.g., from membrane surface glycoproteins) found on host surfaces in contact with blood plasma. Although these polyanion binding sites are not required for FH to regulate fluid phase AP C3 convertase, they are required for its activity on surface-bound C3bBb. In fact, this is the basis for FH being able to discriminate between AP C3 convertase adventitiously deposited on host tissue versus that deposited on a microbial surface because the latter do not possess either the sulphated glycosaminoglycans or the sialic acid arrays.[29,30]

Pathogen surfaces normally are not afforded the protection offered by these regulators. Persistence of the C3bBb convertase on microbial surfaces may additionally be favored by the positive regulator properdin (factor P). This positive modulation of the AP by properdin has traditionally been thought to be attributable to its ability to prolong the lifetime of the AP C3 convertase by forming a C3bBbP complex. This mechanism is still valid, but recently, evidence has been presented that properdin, which circulates predominantly as a homotrimer, may also be able to recognize AP targets directly. Specifically, it has been shown to bind to microbial surfaces, such as to *Neisseria gonorrhoeae* or yeast cell walls, that are known AP activators, but not to strains of *Escherichia coli* that are known to be nonactivators of the AP of complement. Because it is a homotrimer, even if factor P uses two of its subunits to bind to the microbial surface, one is still left that can recruit C3b, or C3(H_2O), from the fluid phase to the microbial surface. The properdin-bound C3b/C3(H2O) can then act as a platform for recruiting factors B and D, thereby forming a surface-bound AP C3 convertase.[31] Consistent with this target recognition model for properdin functionality, individuals with deficiencies in factor P have a heightened susceptibility to infection with *Neisseria* spp.[32]

After forming, the C3bBb convertase rapidly cleaves more C3 to C3b, which can participate in the formation of more molecules of C3bBb convertase. The AP thereby activates an amplification loop that can proceed on the surface of a pathogen but not on a host cell. An additional point regarding amplification by the AP is that C3b deposited on a target as a result of activation of either the CP or the LP can act as a nidus for the formation of an AP C3 convertase.

Although specific antibody is not required for AP activation, many classes of immunoglobulin can facilitate AP activation.[33] The mechanism by which this occurs remains elusive, although some evidence indicates that C3b covalently bound to IgG displays a reduced rate of inactivation to iC3b by factors H and I.[34] However, in contrast to CP activation, which requires Fc, AP activation can occur with $F(ab)'_2$ fragments.

An instructive demonstration for the role of antibody in continuing the AP cascade, with possible ramifications for human disease, comes from a murine model of rheumatoid arthritis. Mice do not spontaneously develop rheumatoid arthritis.[35] However, a murine model has been developed in which expression of antibodies specific for the ubiquitously expressed cytoplasmic protein glucose-6-phosphate can cause joint destruction reminiscent of human rheumatoid arthritis. Interestingly, the disease state, through complement-mediated joint destruction, can occur even if the specific antibodies are of isotypes incapable of fixing complement through the CP. The response may be localized to the joints because of the absence of complement cascade regulators on cartilage.

C3, C5, and the Membrane Attack Complex

The formation of the C3 convertase, C4b2a (CP and LP) and C3bBb (AP), is the point at which the three pathways converge (see Fig. 22-1). The function of these complexes is to convert C3 to C3a and C3b. C3 is the most abundant complement protein in plasma, occurring at a concentration of 1.2 mg/mL, and up to 1000 molecules of C3b can bind in the vicinity of a single C3 convertase.[36]

The covalent attachment of C3b to either C4b2a or C3bBb converts this enzyme into a trimeric complex (C5 convertase) capable of binding and cleaving C5 into C5a and C5b. Mechanistically, the "adduct" C3b molecule increases the binding affinity of the C5 convertase for its substrate C5 such that its K_M is now well below the physiologic concentration of C5 in plasma.[37] C5b is the initiating component of the membrane attack complex (MAC). The MAC is a multiprotein complex whose components are C5b, C6, C7, C8, and multiple C9s.[38,39] The constituent components of the MAC associate in the numerical order C5b–C6–C7–C8–C9.

The MAC, when viewed by electron microscopy, resembles a cylinder that possesses a hydrophobic outer face and a hydrophilic central core. If assembled near a lipid bilayer, such as a cell or the bacterial membrane of a gram-negative strain, the MAC can associate with and insert into the lipid bilayer. Such insertion can be thought as "punching holes" into the membrane, allowing for passage of water and small ions into the cell. Osmotic equilibrium is thereby lost, leading to eventual lysis of the targeted cell or bacterium. C5b678 are sufficient to form small pores in the target membrane. The role of C9 appears to be to enlarge the channel through multiple C9 polymerization, thereby causing more rapid loss of membrane function and lysis. Deficiencies in complement components C5 to C9 have only been associated with increased susceptibility to *Neisseria* spp.–based infections, such as gonorrhea and bacterial meningitis. Also, the extended cell wall peptidoglycan layer of gram-positive strains of bacteria make them resistant to the lytic arm of complement. It can be concluded from these observations that the requirement for MAC is limited in host protection.

Complement Receptors and Their Role in Immune Complex Clearance and Activation

As described in the previous section, complement can act by the direct lysis of targeted cells. Another important function of complement in host protection is facilitating the uptake and destruction of pathogens by phagocytic cells. This occurs by the specific recognition of C3b/C4b–coated (opsonized) particles by complement receptors.[40,41]

The best characterized complement receptor for the uptake of C4-coated immune complexes is CR1 (CD35). CR1 binds C4b/C3b–bearing immune complexes. CR1, similar to most proteins that bind activation products of C4 and C3 molecules, shares a structural motif known as the short consensus repeat (SCR). Each short consensus repeat consists of approximately 60 amino acids. CR1 in humans is composed of 30 linked short consensus repeats. CR1 possesses three binding sites for C4b and two for C3b.

CR1 is expressed on a wide variety of cell types in humans, including erythrocytes, macrophages, polymorphonuclear leukocytes, B cells, monocytes, and FDCs. The role of CR1 expression on B cells and FDCs in activating and maintaining the adaptive immune response is detailed subsequently. For now, the focus is on the other cell types that express CR1.

Because CR1 is not directly associated on its cytoplasmic side with any intracellular signaling molecules, binding of C3b by CR1 expressed on phagocytic cells is not in itself capable of inducing endocytosis of the C3b-opsonized target. A secondary signal is required to induce phagocytosis. This second signal can be provided by IgG binding to the phagocyte's Fc receptor, by carbohydrates commonly found on bacterial surfaces, or by exposure of the phagocytic cell to the appropriate cytokines. In addition, some phagocytic cells, such as macrophages, are activated by binding of C5a through C5a receptor (C5aR, [CD84]) (see Biologic Activity of C3a and C5a, later). What these secondary ligands have in common is that they all bind to receptor domains that are the ligand recognition units of a cell signaling molecule or complex.

The largest pool of CR1-expressing cells is erythrocytes.[42] Erythrocytes bearing opsonized material are removed from the circulation presumably to prevent deposition in tissue sites such as the renal glomerulus. Erythrocytes bearing opsonized material traverse the sinusoids of the liver and spleen, where they come into close contact with fixed phagocytic cells. These phagocytic cells effect the transfer of opsonized material from the erythrocyte onto their own membranes. The transfer of complexes is enhanced by cleavage of C3b to iC3b by FI, as iC3b is a poor ligand for CR1, but is a good ligand for CRIg, a complement receptor of the Ig superfamily present on tissue-resident phagocytic cells (see later for further discussion of CRIg).

Given its central position in the complement cascade, the presence of C3b is tightly regulated. This regulation is brought about by cleaving C3b into inactive derivatives that cannot participate in forming an active convertase. One of the conformationally altered inactive derivatives of C3b, iC3b (see Fig. 22-2, *B*), can act as an opsonin in its own right for complement receptors CR2 (CD21), CR3 (CD11b/CD18) and CR4 (CD11c/CD18). CR3 binds iC3b and plays a major role in inducing phagocytosis but probably not activation in the absence of a second signal (e.g., Fc receptor or pattern recognition receptor). CR4 also binds iC3b-opsonized particles, resulting in direct endocytosis. Although its role as a phagocytic receptor is not well characterized, CD11c is the major marker for DCs. It is important to understand the functional importance of this complement receptor on DC and how it participates in uptake of antigen for presentation to T lymphocytes.

CR2 expressed on B cells augments cognate antibody receptor signaling (see later section). This receptor recognizes targets that are coated with iC3b, as well as the subsequent degradation products C3dg and C3d, all of which remain covalently bound to the target (see Fig. 22-2, *B*). CR2 is the only complement receptor that recognizes C3d/TED as its ligand. However, the CR2 binding site on TED only becomes accessible after degradation of C3 to at least the iC3b stage. Activation of complement plays a contributing role in producing a strong antibody response. An interesting aside is that CR2 is the cell surface receptor on human B cells that is recognized by the Epstein-Barr virus.[43]

CRIg is a recently described complement receptor that plays an important role in the clearance of C3b opsonized complexes by phagocytic cells of the liver.[44] It is also expressed on subsets of macrophages, but less is known about this role. The recent cocrystallization of C3b and CRIg revealed binding to the C3b β chain, which is in contrast to all other known C3-interacting partners, in which binding to the activated C3 occurs via the α chain.

Biologic Activity of C3a and C5a

The role of the complement fragments C3a and C5a in the immune response is to produce localized inflammation.[45] C3a and C5a are anaphylatoxins and are structurally similar to chemokines. When produced in large amounts or injected systemically, they induce a generalized circulatory collapse and shocklike syndrome similar to that seen in a systemic allergic reaction involving IgE antibodies.[46]

Of the two fragments, C5a is the most stable and possesses the best characterized and possibly highest specific biologic activity. Both C3a and C5a induce smooth muscle contraction and increased vascular permeability. C5a and C3a also act on endothelial cells lining blood vessels to induce adhesion molecule expression.[47,48] Additionally, C3a and C5a can activate the mast cells that populate submucosal tissues and line vessels throughout the body to release histamine, tumor necrosis factor α (TNF-α), and protease.[6] The changes induced by C3a and C5a recruit antibody, complement, and phagocytic cells to the site of infection, thereby hastening the adaptive immune response. C5a also induces the upregulation of CR1 and CR3 on the surfaces of these cells. C5a is the only complement chemotactic agent for neutrophils, macrophages, and basophils. By contrast, both C3a and C5a possess chemotactic activity for mast cells.[49] Although a similar fragment, C4a, is produced in the course of C4 activation, its physiologic relevance as an anaphylatoxin is highly questionable. First, human C4a binds to neither C3aR nor C5aR, the two well characterized complement anaphylatoxin receptors, and a specific C4a binding entity has not been identified. Second, anaphylatoxin activity for human C4a has only been reported on guinea pig targets, but even there, it is two to three orders of magnitude less potent than human C3a.[49]

Regulation of Complement Activation

Activation of the complement system must be tightly regulated to prevent autologous tissue damage (see Table 22-1).[50] Some of the proteins involved in regulating complement action have been described (see Alternative Pathway earlier). In addition to these regulators, a number of other checkpoints limit the scope and target of complement activation.

As a result of binding to antibody or pathogen, conformational changes to C1q induce the enzymatic activity of C1r and C1s. Both of these enzymes are regulated by the C1 inhibitor (C1-INH). C1-INH is a member of a family of *ser*ine *p*rotease *in*hibitors termed *serpins*.[51] Serpins provide a bait sequence that mimics the active site of the substrate. When C1r or C1s proteolytically attacks this sequence, the net result is that their respective active site serine hydroxyls become permanently covalently bound to the C1-INH bait site, thereby destroying their proteolytic activity. C1-INH works in a similar fashion in regulating the activated MASP proteases of the LP. Finally, C1-INH is also responsible for preventing spontaneous fluid-phase activation of C1 in plasma, but this activity can be overridden by immune complexes.

Although C1 is capable of cleaving multiple C4 molecules, only approximately 10% of the produced C4b clusters about the targeted antigen.[52] The rest is released into the fluid phase. C4b in the fluid

phase is rapidly bound by C4 binding protein (C4BP), which is a cofactor for FI. Factor I cleaves C4b into two fragments, C4c and C4d, which are quickly cleared from the circulation.

In addition to their FI cofactor activities, the soluble regulators C4BP and FH, respectively, promote the dissociation of the CP (C4b2a) and AP (C3bBb) C3 convertases into their constituent components. This decay-dissociation is unidirectional because neither C2a nor Bb can reassociate on its own with their respective C3 convertase subunits. The membrane-bound regulators CR1 and DAF similarly possess decay-accelerating functionality toward both the CP and AP C3 convertases. The importance of CR1 or CR1-like molecules in curbing the complement response can be witnessed in a rather unexpected condition. Complement receptor 1–related gene (*Crry*) is a murine homologue of the human *CR1* gene, although its near-ubiquitous tissue distribution more closely resembles that of MCP (a somewhat more distant homologue).[53,54] Mice lacking Crry are unable to properly regulate C3. Crry-deficient mice spontaneously abort because of C3-dependent injury to the fetus. This presumably is the result of uncontrolled C3 deposition on the placenta. This observation in mice sheds light on the possibility that MCP (or perhaps CR1) plays a role in recurrent fetal loss manifest in patients with antiphospholipid syndrome.

Biologic Consequences of Complement Cascade Deficiencies

The important role of the complement system in preventing disease is witnessed in cases in which components of the system are absent either because of random mutation in the human population or by design in gene-targeted "knock-out" mice. Some complement cascade deficiencies have been described. This section focuses on the biologic consequences of deficiencies in complement cascade activation that have profound biologic consequences followed by a discussion on deficiencies in complement regulatory proteins.

Homozygous deficiencies in C1q, the most common form of C1 deficiency in humans, is a powerful susceptibility factor for the development of systemic lupus erythematosus (SLE).[55,56] Patients lacking C1q nearly always present with SLE. They have increased susceptibility to viral and bacterial infections, but it is not nearly as pronounced as in C3 deficiency (see later discussion). C1q knock-out mice show increased mortality, with up to 25% of mice having histologic evidence of glomerulonephritis.

C4 in humans is encoded by two separate loci giving rise to two distinct protein products, C4A and C4B.[57] Complete C4 deficiency correlates with a 75% prevalence of SLE in humans. However, at least in certain human populations, the absence, or even haploinsufficiency, of C4A, but not C4B, is associated with elevated risk for development of autoimmune diseases such as SLE and other lupus-like autoimmune disease. The reason for the protective effect of C4A is not settled, but it is worth noting that the one indisputable functional difference between C4A and C4B is in the nature of the covalent bond formed upon target deposition. Whereas C4A transacylates onto amino group nucleophiles, forming amide bonds, C4B shows a strong preference for forming ester linkages to hydroxyl group nucleophiles. The approximately threefold greater propensity of C4A, relative to C4B, to bind to amino-group-rich C1-bearing IgG aggregates,[58] as would be present in immune complexes in need of complement-dependent clearance, is one possible reason for the association of C4A null states with SLE. Finally, as with C1q, mice deficient in C4 are predisposed to SLE-like disease.

C2 deficiency appears to be relatively benign.[59] Humans lacking C2 appear to have a normally functioning immune system, although autoimmune disorders and, less commonly, infections are observed with increased frequency.

In light of the central role of C3 in the complement cascade, it is not surprising that C3 deficiency has dire consequences for the host organism. Of all known cases of C3 deficiency among humans, no patients have been reported as disease free. Infectious complications, predominately pyogenic in nature, occur frequently and recurrently. *Streptococcus pneumoniae* and *Neisseria meningitidis* are the major pathogens reported. In addition, SLE, vasculitic syndromes, and glomerulonephritis have been documented in up to 21% of C3-deficient patients. Mice deficient in C3 show, similar to humans, greatly increased susceptibility to streptococcal infection and death.[60] The 50% lethal dose (LD_{50}) is 50-fold less for C3-deficient mice than for C3-sufficient control subjects. This may be attributable in large part to the inability of mice deficient in C3 to effectively opsonize the bacteria. Moreover, the deficient mice have an impaired humoral response (see later section).

Biologic Consequences of Complement Regulatory Protein Deficiencies

Deficiencies in C1-INH have been observed in the human population.[61] C1-INH deficiency can be inherited as an autosomal dominant trait or can result from autoantibodies that recognize C1-INH, blocking its function.[51] The inherited form of this deficiency is the cause of hereditary angioedema. Patients with hereditary angioedema experience chronic spontaneous complement activation leading to the production of excess cleaved fragments of C4 and C2. The biochemical cause of angioedema in these patients is not definitively elucidated. One line of reasoning points to excess production of C2 kinin and bradykinin. The peptide C2 kinin is a breakdown product of C2a after cleavage of C2. This peptide causes extensive swelling; the most dangerous is local swelling in the trachea, which can lead to suffocation. Bradykinin, which has similar actions to C2 kinin, also is produced in an uncontrolled fashion in this disease as a result of the lack of inhibition of another plasma protease, kallikrein, which is activated by tissue damage and is regulated by C1-INH. Although C1 is unregulated in patients with hereditary angioedema, large-scale cleavage of C3 is prevented by C4 and C2 control mechanisms and by regulation of C3 convertase formation on host cells. An increased risk of infection is not associated with C1-INH deficiency. This disease can be fully corrected by infusion of purified C1-INH.

Acquired C1-INH deficiency may be associated with lymphoproliferative disorders and in most cases represents development of an autoantibody that binds to and neutralizes C1-INH. In two examined cases, autoantibodies abrogate C1-INH activity by preventing formation of the C1s–C1-INH complex. However, after the complex formed, the autoreactive antibodies had no effect on C1-INH function. To date, there is no uniform, fully effective therapy for these patients.

The role of FI in complement cascade regulation can be witnessed in patients with FI deficiency.[62] In the presence of a cofactor protein, FI cleaves C3b, producing iC3b, the inactive form of C3b. iC3b is incapable of reacting with factor B to form the AP C3 convertase, thereby preventing uncontrolled AP activation. In the absence of FI, unrestrained C3 consumption occurs secondary to accelerated spontaneous AP turnover. Patients with FI deficiency have recurrent infections caused by pyogenic organisms, including meningococcal meningitis.

Likewise, mice deficient in the central protein FH exhibit unrestrained C3 activation via the AP, leading to near depletion of serum C3. An important outcome of the failure to regulate C3 activation is glomerulonephritis. Strikingly, mice deficient in FH develop a disease resembling the human disorder membrane glomerulonephritis. The phenotype of the mice confirms the general notion that the AP is always "on" and that failure to regulate activated C3 results in consumption of circulating C3 and tissue injury.

Another example of the importance of FH regulation are reports of genetic association between variant alleles of FH and the human diseases age-related macular degeneration (AMD) and atypical hemolytic uremic syndrome (aHUS). Whereas AMD is a fairly common condition—indeed, it is the leading cause of blindness in the Western world—it has been the elucidation of the etiology of the much rarer aHUS condition (two cases per million) that has led to a fuller appreciation of the diverse ways through which dysregulation of the AP of complement can give rise to severe pathology. Classically, HUS is a

clinical triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The disease is characterized by a precipitating injury of endothelial cells. In contrast to the fairly common classical form of HUS, which is diarrhea associated and is usually caused by a Shiga toxin–secreting pathogen, the atypical form of HUS is nondiarrheal and is caused by genetic predisposition. Even haploinsufficency of variants of FH, MCP, and FI resulting from either loss of expression—or more commonly, loss of regulatory function—results in disease pathology. Additionally, gain-of-function variants of factor B have been described that either form the AP C3 convertase more efficiently than wild-type factor B or are more resistant to decay-dissociation by FH or DAF. Finally, several C3 variants have been described in aHUS patients that are gain of function in the sense that as C3b there is decreased binding affinity for MCP and FH and thus AP C3 convertases formed with this C3b as subunit would have a prolonged lifetime relative to wild type C3b.[63,64]

Because FH mutations account for at least 30% of reported aHUS cases and approximately 70% of these are caused by missense mutations in SCR domains 19 and 20, the molecular basis of this disease association has been intensively investigated, and the findings of these studies are best understood in the context of a structure-based domain model[65] of FH bound to C3b on a nonactivator (i.e., host) surface (Fig. 22-3). FH consists of 20 SCR domains, where some domains in the middle of the molecule appear to play mainly a structural role, likely allowing the molecule to bend back on itself, but domain clusters near the ends mediate specific functions. SCRs 1 to 4 bind to C3b and mediate both decay-accelerating and FI-cofactor functionalities. Indeed, FH(SCR1-4) on its own is able to regulate a fluid-phase AP C3 convertase, but it cannot do so for surface-bound AP C3 convertases. For regulation of the latter, there are three additional binding interactions that become relevant. Two of these are located within SCRs 19 to 20, specifically, a site localized mainly to SCR19 binds to the C3d/TED domain of the surface-bound C3b molecule, and a site within SCR20 binds to surface-associated polyanions such as sulphated glycosaminoglycans or sialic acid arrays. The aHUS-associated missense mutations found within SCRs 19 to 20 affect one or other of these two binding functions and lead to dysregulation of the AP C3 convertase at the surface of host tissue. In particular, complement-mediated damage to the kidney basement membrane is often a hallmark of aHUS. As a tissue devoid of the membrane-associated complement regulators MCP, DAF, or CR1, but rich in sulphated glycosaminoglycans, the functionality of the soluble AP regulator FH becomes even more crucial for host protection and likely explains the high incidence of missense mutations within SCRs 19 to 20 in aHUS patients. Interestingly, missense mutations in FH SCRs 19 to 20 do not result in systemic C3 consumption, as would be the case for complete deficiencies of FH. This is because SCRs 1 to 4 of the mutant molecule are still capable of regulating spontaneously formed AP C3 convertases in the fluid phase.

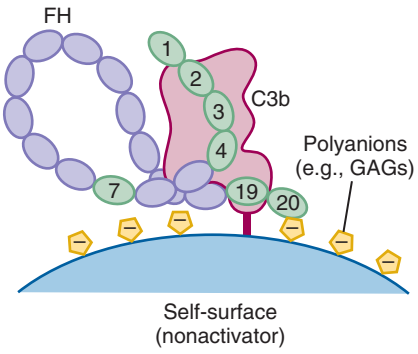

Figure 22-3 A STRUCTURE-BASED MODEL OF THE FACTOR H (FH)–MEDIATED REGULATION OF THE ALTERNATIVE PATHWAY ON HOST CELLS BEARING ADVENTITIOUSLY DEPOSITED C3b. Whereas the depicted interaction of FH domains SCR(1-4) with C3b is sufficient to prevent C3b in solution from becoming a subunit of an AP C3 convertase, for surface-bound C3b, at least two additional interactions are necessary. The first is the interaction indicated between FH SCR19 and the thioester domain (TED)/C3d domain of the C3b molecule. The second is between FH SCR20 and cell surface–associated sulphated glycosaminoglycans (GAGs) or arrays of sialic acid containing glycans, in both cases denoted by *pentagons with an internal minus sign*. Mutations affecting either the C3d binding site or the polyanion binding site within FH SCR(19-20) lead to alternative pathway dysregulation and the disease atypical hemolytic uremic syndrome (aHUS). There is an additional polyanion binding site in SCR7, which appears to be important for regulating the AP on some host surfaces, most particularly Bruch's membrane in the eye because the SCR7 Y402H polymorphism is a risk factor for AMD. *(Adapted from Kajander T, Lehtinen MJ, Hyvärinen S, et al: Dual interaction of factor H with C3d and glycosaminoglycans in host-nonhost discrimination by complement.* Proc Nat Acad Sci U S A *108:2897, 2011; reproduced with permission of the National Academy of Science.)*

In addition to the polyanion binding site in FH SCR 20, there is also one in SCR 7. This SCR is the site of an amino acid polymorphism in FH (tyrosine to histidine at residue 402, Y402H) that is a significant risk factor for AMD but interestingly does not correlate with disease susceptibility for aHUS. Heterozygotes and homozygotes for H402 are respectively 2.7-fold and 7.4-fold more at risk for AMD than homozygous Y402 individuals, and this single polymorphism can account for up to 50% of the risk of AMD.[66,67] Two significant functional differences have been observed for the Y402 and H402 variants of FH. First, the affinity and specificity for a spectrum of sulphated glycosaminoglycans is different for the two variants of FH. Secondly, the affinity of the H402 variant of FH for C-reactive protein (CRP), an acute-phase protein that binds to damaged tissue, is substantially lower than that of the Y402 variant. It is notable that Bruch membrane of the macula, similar to the kidney basement membrane, is devoid of membrane-associated complement regulators and so is highly dependent of FH for local AP regulation. Indeed, the spectrum of sulphated glycosaminoglycans found on Bruch membrane appear to be more dependent on the polyanionic binding site in SCR 7 for the interaction than that in SCRs 19 to 20 because even with non-AMD eye tissue, there is preferential binding of the Y402 variant to Bruch membrane.[68] Thus, the lower binding affinity of the H402 FH variant, coupled with a possible age-related change in the bisynthesized spectrum of sulphated glycosaminoglycans on Bruch membrane, could account for the dysregulation of the AP in the macula with the ensuing inflammation of the macula seen in AMD patients. There may also be a contribution from the differential binding of the FH variants to CRP present on the particulate debris (drusen) residing in between the retinal pigment epithelium and Bruch membrane.

The MAC is one mechanism used by the host to rid itself of certain microorganisms. Host cells are protected from MAC-mediated lysis by CD59 (protectin), a membrane-bound protein. CD59 performs its function by inhibiting the binding of C9 to the C5b–C6–C7–C8–C9 complex. CD59 and DAF are linked to the cell surface by a phosphoinositol glycolipid (PIG) tail. One of the enzymes involved in the synthesis of PIG tails is encoded on chromosome X. Mutation of this gene leads to a failure to synthesize PIG tails and with it an inability to express CD59 or DAF on the cell surface.[60-71] Lack of CD59 and DAF expression on host cell surfaces is the cause of paroxysmal nocturnal hemoglobinuria. This disease is characterized by episodes of chronic intravascular hemolysis and propensity to thrombosis.

Autoimmunity and Complement Deficiencies

There exists a strong correlative relationship between the lack of certain components of the complement system (i.e., C1 and C4) and autoimmune disease, particularly SLE. Two general nonmutually exclusive hypotheses have been put forward to explain the increased incidence of SLE among complement deficient individuals—the clearance hypothesis and the tolerance hypothesis.[56,72,73] The clearance hypothesis is based on the known role of the CP of complement in

binding to foreign antigens and transporting them to the liver and spleen for degradation and removal from the circulation. Thus, defects in clearance of apoptotic cells or debris would lead to inappropriate accumulation of self-antigen and overstimulation of self-reactive lymphocytes.

The tolerance model proposes that innate immunity protects against SLE by delivering lupus autoantigens to sites where immature B lymphocytes are tolerized, thereby eliminating a source of autoreactive antibody molecules. SLE is characterized by high-affinity antibodies specific for autoantigens such as double-stranded DNA (dsDNA), ribonuclear proteins, and histones. Validation of the model comes in part from studies with human B cells demonstrating that self-reactive B cells are eliminated or anergized at two major checkpoints, bone marrow (BM) and spleen. Thus, counterselection of potentially pathogenic B cells is an active process and most likely involves components of innate immunity.

Recent studies in a mouse model (strain 564 Igi) in which the B cells express an Ig receptor specific for the lupus antigen SSB/LA suggests a third possible explanation for why C4 is critical for protection against SLE. Accordingly, this hypothesis suggests that C4-dependent defects in clearance of immune complexes leads to a loss of tolerance of certain autoreactive B cells. Thus, accumulation of immune complexes composed of lupus antigens that bear DNA or RNP ligands that trigger Toll-like receptors (TLRs) TLR 7 and TLR 9 may induce myeloid cells to release excess type I interferon (IFN-α). In a feed forward loop, IFN-α release induces increased sensitivity of TLR 7 and 9 receptors, in particular on B cells, such that the combined effects of engagement of DNA or RNP self-antigen and increased TLR 7 and 9 leads to escape of B-cell tolerance (MCC, unpublished).

The first part of this section familiarized the reader with the general aspects of the complement system. The remainder of this section focuses on the role of the complement system in the initiation and propagation of the adaptive immune response and begins with a description of natural antibody.

Natural Antibody

Natural antibody, in contrast to antibody secreted in response to active immunization, is continuously released, mostly by the B1 subpopulation of lymphocytes. Predominantly IgM but also IgA and IgG3 (in mice), natural antibodies tend to be polyreactive, with low-affinity binding for antigens such as nuclear proteins, DNA, and phosphatidylcholine, which are common structures among both pathogens and host tissue. These antibodies rarely show evidence of somatic mutation. It has been speculated that the variable region genes that predominate among natural antibodies have been selected evolutionarily for their ability to recognize pathogens and act as a rapid response to infection, thereby acting as a stop gap to provide sufficient time for the adaptive immune response to form. Natural antibody mediates its protective effects via the CP of complement.

IgM natural antibody is important in initiating the CP, leading to enhanced humoral immunity. In addition to its role in protecting against pathogens, natural antibody protects against lupuslike disease based on studies in mice. Thus, similar to C1q and C4, deficiency in IgM predisposes to an SLE-like phenotype.

Complement Links Innate and Adaptive Immune Responses

One of the critical functions of CP complement is providing a bridge between innate and acquired immune systems. The process is achieved through attachment of complement products to the antigen or pathogen, either directly to the surface or via antibody (see earlier section). This complement "tag" consists of breakdown products of C3 (i.e., C3b, C3dg, and C3d) that facilitate recognition of pathogens by the immune system. The recognition phase is mediated principally through complement receptors CD21 (CR2) and CD35 (CR1). This section details complement-dependent mechanisms of immune detection and humoral responses to thymus (T)-dependent antigens.

Soluble Complement Mediators of Antibody Responses

The first clue that complement is important in regulating B-lymphocyte responses came from the observation that B lymphocytes bind activated C3 fragments.[74] Soon thereafter, it was noted that mice depleted of serum C3 by treatment with cobra venom factor had diminished responses to T-dependent antigens.[75] The discovery of naturally occurring genetic deficiencies in C3, C4, and C2 in species as diverse as guinea pigs,[76,77] dogs[78] and humans[79,80] allowed description of impaired antibody responses as well. Because the impaired responsiveness is comparable among animals deficient in CP activators (C4, C2) and C3-deficient or C3-depleted animals, a model emerged suggesting that the effect is mediated through the CP of the complement system. That the impaired responsiveness is comparable among diverse animal species indicated the importance of CP complement in regulating antibody responses to T-dependent antigens.

The advance of gene-targeting technology in the murine system led to development of engineered strains devoid of various components of CP complement. C1q-, C4-, and C3-deficient mouse strains generate reduced antibody responses to T-dependent antigens.[81-84] Furthermore, these strains fail to switch Ig isotypes normally, suggesting that germinal center responses are impaired.[83] Germinal centers are microanatomic structures whose purpose is to provide for increasing affinity of serum antibody for antigens (affinity maturation), isotype switching, and development and differentiation of memory B lymphocytes and plasma cells.[85] Consistent with this theory, immunized complement-deficient mice produce fewer and smaller germinal centers compared with immunized wild-type mice.[83] Importantly, humoral responses in each of the C1q-, C4-, and C3-deficient strains can be rescued by transplantation of wild-type BM.[55,86,87] Therefore, BM-derived cells can produce sufficient complement to reconstitute antibody responses to T-dependent antigens administered intravenously.

It is suggested that the CP potentiates antibody responses through involvement of immune complex formation. The implication is that natural antibodies or specific IgM released early in the response by B cells responding to antigen recognize and bind pathogens, thereby activating the CP. In support of this model, genetically engineered mice producing only membrane IgM (i.e., with gene-targeted deletion of secretory signals) produce significantly reduced antibody responses to T-dependent antigens.[88] A second mechanism for initial CP activation on the antigen, which may be relevant to a subset of antigens bearing a repeating epitope, involves binding of the antigen by B cells through the surface IgM of two or more B-cell receptors (BCRs). The cross-linking and distortion that is imparted to the Fc_{μ} regions of adjacent BCRs is sufficient to activate the CP at the B-cell surface. Indeed, this mechanism does not work if the BCR μ-chain contains a mutation that abolishes C1q binding.[89] Finally, a third permutation of these mechanisms may apply to monovalent soluble T-dependent antigens. The antigen is first captured by the BCR, creating an antigen array on the B-cell surface, to which low-affinity natural repertoire IgM can bind by virtue of avidity effects and initiate the CP.[90] As illustrated by these examples, immune complex formation is only important for initiating the CP, leading to the deposition of C3 activation products on the antigen or immune complex. Indeed, antigens directly conjugated to C3b or C3d fragments are more potent immunogens compared to unconjugated antigen.[91,92] Furthermore, the magnitude of the immune response is directly influenced by the number of C3d fragments conjugated to the antigen.[91] Therefore, activated products of complement component C3 act as a natural adjuvant in driving efficient antibody responses.

Complement Receptors and Antibody Responses

B-Lymphocyte Coreceptors

The effects of complement-coated antigens on antibody responses are mediated primarily through complement receptors CD21 and CD35. CD21 and CD35 are expressed predominantly on B lymphocytes and FDCs.[93,94] CD35 is also found on polymorphonuclear cells, macrophages, mast cells, and DCs.[93] CD21 and CD35 are encoded for by separate yet closely linked genes in humans.[95] In mice, CD21 and CD35 originate from the same locus (Cr2) and are generated by alternative splicing events at the RNA level.[96,97]

Two novel sets of experiments demonstrated that CD21 and CD35 are important in regulating B-lymphocyte responses to T-dependent antigens. In the first set of experiments, antibodies specific for both CD21 and CD35 or CD35 alone were administered to immunized mice.[98-101] In the second set of experiments, a soluble form of CD21 was administered to immunized mice, thereby competing for C3d-coupled antigen interactions.[102] In both sets of experiments, treatment impaired antibody responses. In the first approach, the antibody that specifically blocked the interaction of C3d with CD21 was much more effective at blocking antibody responses compared with anti-CD35 antibody treatment, which blocked only the binding of C3b to CD35. This suggested that although both receptors contribute, CD21 is more important in regulating antibody responses.[99]

Because CD21 and CD35 are found on B lymphocytes and FDCs, two important cell types for humoral responses, two nonmutually exclusive models are proposed for their function. In the first model, CD21 augments antibody responses through activity as a coreceptor on B lymphocytes[103] (Fig. 22-4, *A*). The second model proposes that CD21/CD35 on FDCs trap and focus antigen such that B lymphocytes can efficiently cross-link their antigen receptor to become activated[104] (see Fig. 22-4, *B*).

As is apparent from the schematics in Fig. 22-4, *A* and *B* and as will be elaborated upon further in the ensuing discussion, the key ligand receptor–receptor interaction mediating the linkage between complement and the adaptive humoral immune system is that between the C3d fragment that is covalently coupled to antigen and CD21 (CR2) present on B cells and FDC. The extracellular region of CD21 is composed of 15 or 16 SCR domains (because of the usage of alternative splice sites for exon 11), but the C3d binding site is confined to the two *N*-terminal–most SCR domains.[105] In what is an instructive lesson on the need to have concordance between x-ray crystallographic structures and biochemical data, the nature of this important interface had been hotly debated for the past decade because of discrepancies between a structure of the CR2(SCR1-2):C3d complex published[106] in 2001 with both preexisting and subsequent biochemical data in the literature. A recent de novo structure of this complex[107] depicted in Fig. 22-4, *C* appears to have resolved the issue because the interactions seen in the new structure are fully supported by the biochemical data in the literature. For example, the biochemical data suggesting that there should be multiple ionic bonds mediating the binding is fully rationalized in terms of the five such bonds seen in the structure between a very negatively charged interface on a concave face of C3d that is remote from the covalent attachment site and positively charged lysine and arginine side chains from CR2 sticking down and interacting with oppositely charged residues on the C3d interface, as can be appreciated in Fig. 22-4, *C*.

As a coreceptor, engagement of CD21 by complement-coupled antigen on the surface of a B lymphocyte, in combination with membrane Ig (BCR) cross-linking, would lower the strength of signal through the BCR to activate the cell.[103] Accordingly, naïve B lymphocytes bear low-affinity receptors for antigen; therefore, especially under conditions of limiting antigen, as would be the case during initial encounter with a microbial pathogen, additional signaling by the CD21 coreceptor is required for efficient activation. This was demonstrated in vitro by culturing B lymphocytes with cognate antigen, either uncoupled or coupled to C3d. By measuring intracellular Ca^{2+} levels as a measure of cell activation, it was estimated that 100- to 1000-fold less C3d-conjugated antigen was required to activate B lymphocytes compared with unconjugated antigen.[91]

The opportunity to test the importance of CD21 and CD35 as B-lymphocyte coreceptors in vivo came from studies using mice with targeted disruption in the *Cr2* locus. Importantly, *Cr2*-deficient mice have impaired humoral responses similar to C1q-, C4- and C3-deficient mice (Fig. 22-5).[108-110] Using embryonic stem cells with a disrupted *Cr2* locus, Croix et al[111] used blastocyst complementation of $Rag2^{-/-}$ mice, such that chimeric mice expressed CD21/CD35 on FDCs but not on B lymphocytes. These chimeric mice displayed impaired antibody responses to the T-dependent antigen NP-KLH compared with control subjects. Therefore, CD21/CD35 on B lymphocytes is important for normal antibody responses. Although CD21/CD35 on FDC is on its own insufficient for normal antibody responses, as discussed in the next section, CD21/CD35 on FDC does have a specific role in the memory response of B cell–mediated immunity.

Complement's covalent attachment to antigen engages CD21 as a complex with CD19/CD81 and BCR on the cell surface (see Fig. 22-4, *A*).[103,112,113] Dual binding of CD21/CD19/CD81 with BCR generates a stronger signal compared with BCR engagement alone.[103] If the combined signal is sufficient, the B lymphocyte is activated. If insufficient, then the B lymphocyte likely is eliminated by apoptosis.[86,114-118] The major ligand-binding receptor within the CD21/CD19/CD81 complex is CD21. CD19's major role is in initiating a signaling cascade within the cell.[119] CD81 is a tetra-spanning molecule that stabilizes the complex within the membrane. After co-ligation of the BCR with the CD21/CD19/CD81 complex, CD81 gets S-palmitoylated on a cysteine side chain, and this in turn mobilizes the co-ligated complexes to a special compartment of the plasma membrane known as a lipid raft. Localization to this compartment facilitates prolonged intracellular signaling because the compartment is rich in signal-propagating phosphokinases but is relatively devoid of the regulatory phosphatases.[120] Absence of any of the CD21/CD19/CD81 components adversely affects antibody responses to T-dependent antigens, although the degree of impairment varies.[108,121-123]

Focusing Antigen on Follicular Dendritic Cells

The second role of complement receptors CD21 and CD35 in regulating humoral responses is that they permit FDCs to trap antigen (Fig. 22-6).[104,124] FDCs concentrate in regions of ongoing immune responses, such as germinal centers, and they appear necessary for antibody responses. Germinal centers (see earlier section) promote somatic hypermutation within Ig heavy- and light-chain genes along with isotype switching and production of memory B lymphocytes and plasma cells. They can be divided into two regions, dark zone and light zone. To gain entry into the dark zone, B lymphocytes are activated by receiving above threshold signals from the CD21/CD19/CD81 and BCR in combination with costimulation from helper T lymphocytes.[125-127] Within the dark zone, activated B lymphocytes divide and mutate their Ig receptor genes.[126-129] After several rounds of proliferation in the dark zone, B lymphocytes enter the light zone, where they are subjected to selection on antigen deposited on FDCs (i.e., clonal selection).[130,131] The selection of high-affinity B lymphocyte clones into memory B-lymphocyte and plasma cell pools ensures future protection against repeat antigen exposure.

How antigen is retained on FDCs, both for primary B-lymphocyte responses and for long-term memory responses, is subject to intense research. However, supporting evidence indicates that complement receptors on FDCs are important in both short- and long-term B-lymphocyte responses. Papamichail et al[104] demonstrated that retention of antigen–IgG immune complexes on FDCs was reduced upon depletion of C3 using cobra venom factor. Therefore, it appears that immune complex deposition on FDCs is complement dependent. In addition, antibody production in vitro using FDCs demonstrates that antibody production is dependent on CD21/CD35.[132]

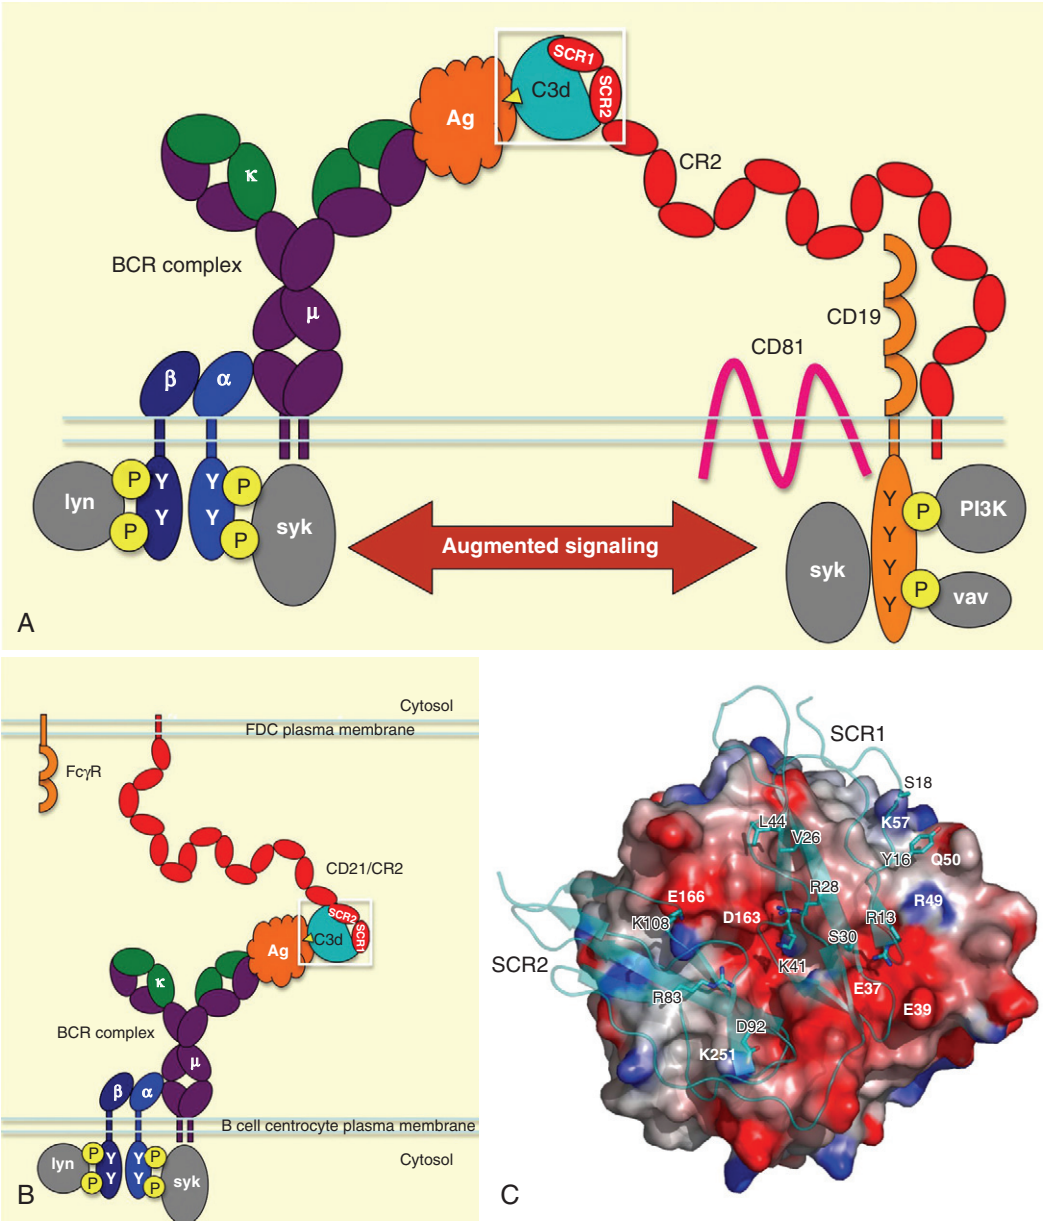

Figure 22-4 COUPLING OF C3D TO ANTIGEN ALTERS ITS FATE IN B-CELL RESPONSE. **A,** Coligation of the B-cell receptor (BCR) with the CD19/CD21/CD81 complex by antigen coated with C3d regulates essential functions for naïve B-cell activation. The *boxed area* indicates the key binding interaction between CD21/CR2(SCR1-2), and the C3d fragment that is covalently bound *(yellow triangle)* to the antigen recognized by this B cell's BCR. **B,** C3d-coated antigens are also captured on the surface of the follicular dendritic cells (FDCs) by CD21, allowing for efficient stimulation of previously antigen-engaged B-cell centrocytes in the germinal centers during the process of affinity maturation and the generation of memory B cells. **C,** The structure of the CR2(SCR1-2):C3d complex as a surface representation of C3d colored for electrostatic potential (*red,* negative; *blue,* positive) and an overlayed, semi-transparent, ribbon diagram of CR2(SCR1-2) showing stick models of the side chains of some of the interacting residues. Availability of *Cr2*-deficient mice has shed light on the importance of FDC-derived CD21/CD35 on humoral responses. Because FDCs are radioresistant, it was possible to generate chimeric mice that restricted CD21/CD35 expression to B lymphocytes by BM transplantation. Ahearn et al[108] made chimeric mice with *Cr2*-deficient FDCs by transplanting wild-type BM (B-lymphocyte $Cr2^{+/+}$) into lethally irradiated *Cr2*-deficient recipient mice (FDC-$Cr2^{-/-}$). After secondary challenge with antigen, the chimeric mice failed to sustain high-level antibody production, suggesting that CD21/CD35 on FDCs is important for recall or memory responses. Fang et al[133] came to a similar conclusion regarding the importance of CD21/35 expression on FDC for a strong immune response.

CD21/CD35 do appear important for persistence of antibody titers, normal frequencies of memory B lymphocytes and plasma cells, and affinity maturation. Adoptively transferring memory B lymphocytes into recipient mice lacking FDC-derived CD21/CD35 demonstrated that complement receptors on recipient mice stroma were required for each of these elements of memory.[114] Importantly,

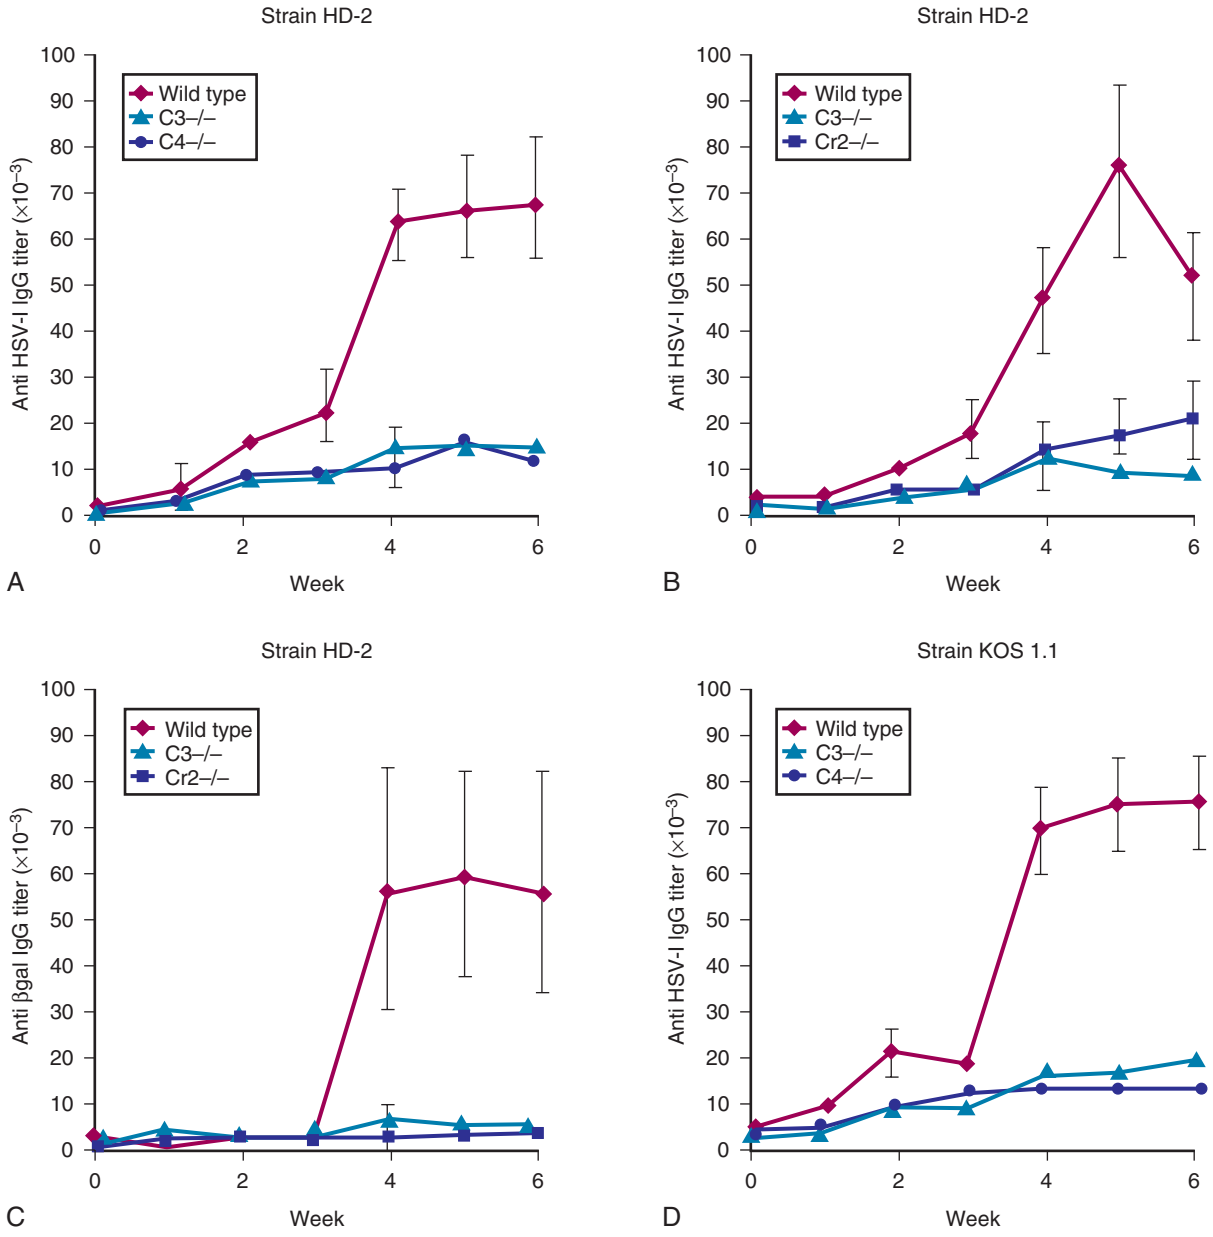

Figure 22-5 Classical pathway complement and complement receptors CD21/CD35 are required for the humoral response to replication-defective HD-2 virus or replication-sufficient KOS1.1 wild-type (WT) virus. Mice were injected at days 0 and 21 with 2×10^6 plaque forming units of replication-defective **(A** to **C)** or replication-sufficient **(D)** virus, HD-2, and KOS1.1, respectively. Antibody titers were determined by enzyme-linked immunosorbent assay. Mean titer ± SD represents at least five mice analyzed in two separate experiments. **A,** Deficiency in either C3 or C4 results in an impaired secondary humoral response to infectious herpes simplex virus (HSV). **B,** Cr2–/– mice have an impaired secondary response similar to mice deficient in C3. **C,** Humoral response to recombinant virus-expressed heterologous protein (β-galactosidase) is also impaired in mice deficient in C3 or CD21/CD35. **D,** Secondary humoral response to replication-sufficient HSV-1 (strain KOS1.1) depends on complement C3 and C4. *(From Da Costa XJ, Brockman MA, Alicot E, et al: Humoral response to herpes simplex virus is complement-dependent.* Proc Nat Acad Sci U S A *96:12708, 1999; reproduced with permission of the National Academy of Science.)*

chimeric mice lacking CD21/CD35-bearing FDCs had severely impaired recall responses several months after transfer of memory B lymphocytes compared with wild-type recipients.[114] These studies suggest that CD21/CD35 on FDCs have an important role in long-term storage of antigen, thereby facilitating B-lymphocyte memory.

Complement and T-Cell Immunity

The complement system is important not only in humoral immunity; it also enhances responses by both CD4 and CD8 T cells.[134] Studies with influenza in C3-deficient mice first identified an important role for C3 in both the CD8 and CD4 response to infectious virus.[135] Although the mechanism is not clear, given the importance of DC in uptake and presentation of antigen, one likely role is C3 opsonization of virus. Moreover, the anaphylatoxins C3a and C5a released during complement activation stimulate cytokine releases by mast cells via their respective complement receptors. Studies of mice deficient in C3a receptor identified reduced responsiveness of a subset on CD4 T cells.[136] Likewise, C5a receptor appears to play an important role in the lung in T cell–dependent allergic responses.

T-cell responses are also "tuned down" via complement receptor. Interestingly, cross-linking of the CD46 complement receptor via C3b on activated CD4 T cells induces differentiation to a T-regulatory

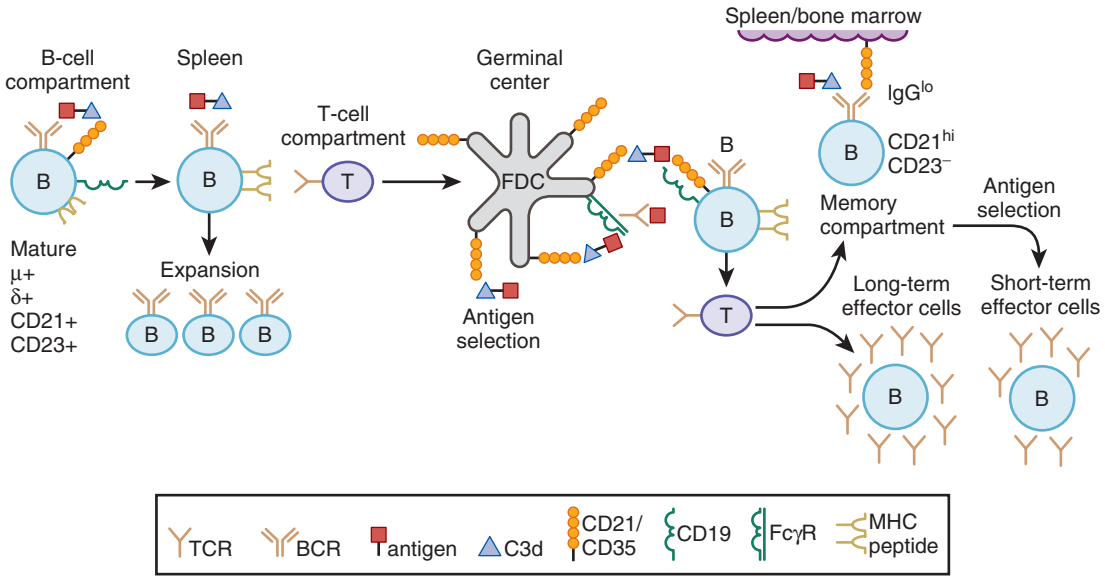

Figure 22-6 ROLE OF COMPLEMENT-TAGGED ANTIGEN IN DIRECTING B-LYMPHOCYTE ACTIVATION AND FORMATION OF MEMORY B LYMPHOCYTES. Mature B lymphocytes survey secondary lymphoid tissues in search of antigen. Survival of mature B lymphocytes after antigen contact and T-cell help within splenic follicles depends on coreceptor signals through CD21/CD35. Lymphocytes receiving requisite signals expand and continue to differentiate within germinal centers, where CD21/CD35 is again important. B lymphocytes not receiving complement–ligand interactions in germinal centers die. In addition, complement-mediated deposition may localize antigen to follicular dendritic cells (FDCs), thereby providing the substrate for B-lymphocyte selection. Selection and differentiation in germinal centers lead to production of long-lived memory B lymphocytes and effector cells. The lifespan of memory B lymphocytes may also depend on continued interaction of antigen deposited on FDCs with CD21/CD35 in the spleen and in bone marrow. *IgG*, Immunoglobulin G.

phenotype.[137] Further investigation on this topic will reveal additional examples whereby the complement system participates in activation and regulation of T cells.

Conclusion

Over the past 15 years, a new appreciation for the complement system has come to light. Not only is the complement system required for host protection and innate immunity, but it also plays a critical role in "directing" the humoral response to thymus-dependent and -independent antigens. Covalent attachment of split products of C3 (i.e., C3d) alters the fate of antigen and targets it to FDC within the lymphoid compartment. Other studies are uncovering additional roles for complement in the regulation of self-reactive B cells. The next decade likely will witness a similar revolution on our understanding of how complement participates in protection against autoimmune diseases such as SLE.

IMMUNOGLOBULINS

Properties and Structure

The mammalian immune system responds to the almost unlimited array of antigens by producing antibodies that react specifically with the molecules that induced their production. During the immune response, the structure of the inducing antigen is imprinted on the immune system, and subsequent challenges with the same or structurally related molecule(s) causes a more rapid rise in antibody levels to much greater concentrations than were achieved after the primary antigenic challenge. Thus, the hallmarks of the humoral immune system include induction, specific protein interaction, and memory.

Antibodies belong to the family of proteins called the *immunoglobulins*. The basic structure of all immunoglobulins consists of a monomer that contains four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains covalently linked by disulfide bonds (Fig. 22-7).[138] The x-ray crystallographic structure of a monomeric immunoglobulin, specifically a mouse IgG2a monoclonal antibody (mAb), is shown depicted in both ribbon and space-filling models in Fig. 22-8.[139] Depending on the angle between the constituent Fab (fragment antigen-binding) monomers, an immunoglobulin monomer consists of a Y- or T-like structure. The size of the Fab arms is 80 × 50 × 40 Å, and the size of base, called the Fc (fragment crystallizable) region, is approximately 70 × 45 × 40 Å according to the x-ray structure models. The Ig molecule exhibits considerable flexibility. In electron microscopic, low-angle x-ray scattering, transient electric birefringence, and resonance energy transfer studies, the angle between the Fab domains has been observed to vary from 0 to 180 degrees. All antibodies have two identical combining sites for each antigen located at the ends of the Fab domains.

Fab and Fc represent functional domains in immunoglobulins. They were discovered by performing limited proteolytic digestion of the molecule. Both the H and L chains contribute amino acids that constitute the antigen-binding site in Fab. The monovalent Fab fragment will bind to, but will not precipitate, multivalent antigens, in contrast to native IgG. A fragment can be prepared, called $F(ab')_2$, that is devoid of Fc but still precipitates antigen. This form of immunoglobulin consists of two Fabs disulfide bonded at a part of the molecule called the *hinge region*. The hinge region is the part of the Ig molecule that is responsible for the molecular flexibility exhibited by all immunoglobulins. The other major function of immunoglobulins, binding to specific receptors on cells and certain effector proteins such as C1q, is associated with binding site(s) also found in Fc. The Fc region of IgG, one of the classes of immunoglobulin, also interacts with protein A, an immune evasion molecule on the cell walls of *S. aureus*. When bound to protein A, the binding of IgG to host effector molecules such as C1q is sterically interfered with.

The chain structure of immunoglobulins explains neither antibody structural diversity nor antibody binding to antigen. The discovery of variable and constant regions of amino acid sequence formed the basis for understanding both phenomena. Thus, in the L

V_H, C_{H1}, V_L, and C_L homology domains are shown as *boxes*. Only the disulfide linkages that join H and L chains are shown. *Left,* Approximate boundaries of the complementarity-determining region (CDR) regions in the V_L and V_H regions. *Right,* Sequences encoded by V_H, D, J_H, V_L, and J_L segments in the V_H and V_L regions.

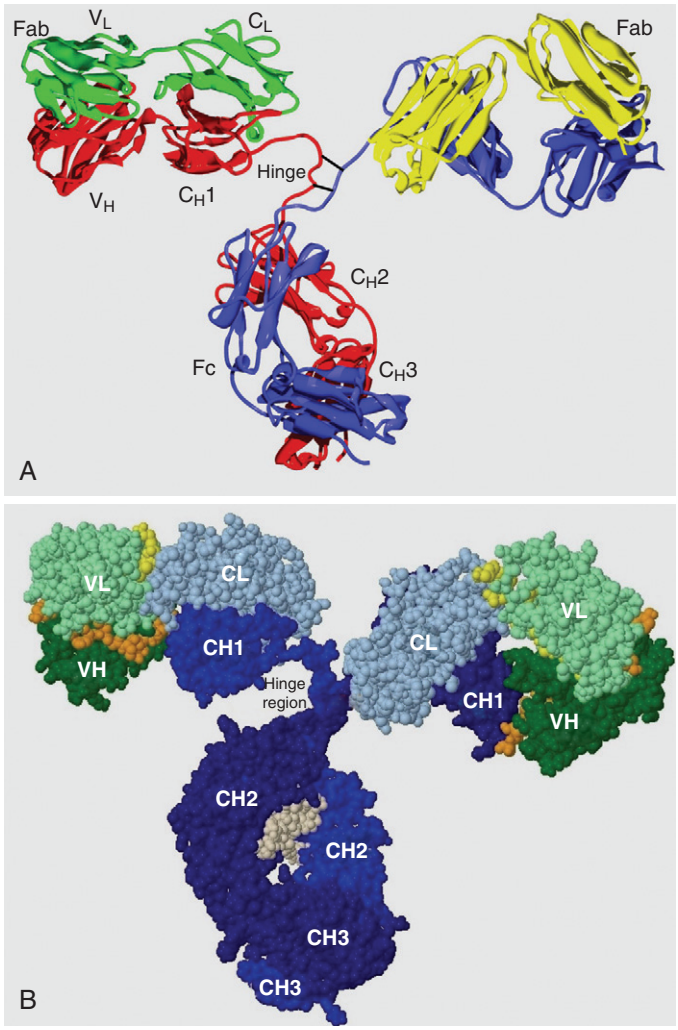

Figure 22-8 X-RAY CRYSTALLOGRAPHIC STRUCTURE OF AN INTACT IgG MOLECULE shown as a ribbon diagram **(A),** or a space-filling model **(B).** The structure is that of a mouse immunoglobulin G2a (IgG2a) monoclonal antibody (protein data base (PDB) file 1IGT) and it was the first intact IgG to have its structure determined. **A,** The two-layer β-sandwich characteristic of the "immunoglobulin fold" is clearly visible within each of the constituent domains of the γ-heavy chains *(blue and red)* and κ-light chains *(green and yellow)*, respectively. *Black lines* indicate the positions of inter-heavy chain disulfide bonds in the hinge region. **B,** The constant domains of the heavy chains and light chains are in various shades of *blue,* and the glycan chain lining a region between apposing C_H2 domains is in *white*. The variable regions are colored according to the genetic segment encoding them. *Dark green* denotes the polypeptide region encoded by the V segment of V_H and *orange* the DJ segment of V_H. *Light green* denotes the polypeptide encoded by the V segment of V_L and *yellow* that encoded by the J segment of V_L. *(**A** modified from http://www.proteopedia.com/wiki/images/4/4a/Opening_1igt.png; **B** from http://www.imgt.org/IMGTeducation/Tutorials/IGandBcells/_UK/3Dstructure/Figure2.html.)*

chain, the 100 or so amino acids in the amino-terminal half of the protein (variable region [V_L]) vary among antibody molecules, but in the second half (constant region [C_L]), there is virtual complete correspondence in amino acids, position for position, to the carboxy-terminus. The H chains exhibit a similar pattern and can be divided likewise into V_H and C_H1, C_H2, and C_H3. Comparison of the amino acid sequence of many V_Ls has revealed that whereas certain parts of the variable region exhibit excess variability, others are less variable. The former regions are called *hypervariable* or *complementarity-determining regions* (CDRs). The latter framework regions function as a structural scaffold to support the CDRs. Antigen binding is mediated by six CDRs, three in each of the V_H and V_L domains. The combining site for antigen is a trough, cavity, or even flat surface composed of parts of the hypervariable regions of both the H and L chains. It is a small region, representing only 25% of the antibody V region. The region that interacts directly with the epitope on the antigen is even smaller and is formed by the association of the CDR regions, each of which consists of approximately 20 amino acids. Thus, the variation in a few amino acids accounts for the specificity and diversity of antibodies with respect to antigen binding.[140]

Immunoglobulins exhibit additional physical heterogeneity, which imparts to each immunoglobulin a special effector function that is reflected in unique biologic properties independent of antigen-binding activity. In the pre-genome era of immunochemical research, heterologous and autologous antisera raised against immunoglobulins were used to classify three types of physical heterogeneity. The first kind is based on the antigenic heterogeneity exhibited by immunoglobulin when it is used as an immunogen in other species. This is called *class* or *isotypic variation*. In humans, five isotypes can be distinguished based on unique antigenic (isotypic) determinants found on the H chain. These are designated by capital Roman letters as IgG, IgM, IgA, IgD, and IgE. The H chain of each class is designated by the lower case Greek letter corresponding to the Roman letter of the class. Thus, the H chain for IgG is γ, for IgM is μ, for IgA is α, for IgD is δ, and for IgE is ε. Some of the immunoglobulin classes are composed of polymers of the basic monomer. In humans, the two antigenic varieties of the L chain are kappa (κ) and lambda (λ). Each Ig has two identical L chains; the κ and λ are shared by all classes. The monomeric form of any immunoglobulin is described by its chain structure. The molecular mass of the immunoglobulins can vary from 150 to 1000 kDa. This variation is attributable to

polymerization of the basic monomer form. None of the immunoglobulins are polymeric forms of another class. IgG is the most prevalent, constituting 75% of the total Ig in blood. It is present in normal adults at concentrations of 600 to 1500 mg/dL. IgG is designated γ2κ2 or γ2λ2. It is the only class of Ig that crosses the placenta (Table 22-2).[141]

The isotype IgM is predominantly a pentamer consisting of five monomeric units disulfide linked at the C-terminus of the H chain. Each monomer of IgM is 180 kDa because of the presence of an additional C_H domain, specifically the Cμ2 domain, which replaces the hinge segment. The complete protein has a sedimentation coefficient of 19 S, which corresponds to a molecular mass of 850 kDa. IgM is designated $(\mu 2\kappa 2)_5$ or $(\mu 2\lambda 2)_5$. IgM also contains a 15-kDa protein called the *J chain*. In the current structural model of IgM, the J chain forms a disulfide-bonded clasp at the C-terminus of two H chains (Fig. 22-9).[138]

The structure of the other isotypes of immunoglobulins are summarized as follows. The isotype IgA has a variable number of monomeric units and is designated $(\alpha 2\kappa 2)_n$ or $(\alpha 2\lambda 2)_n$, where n = 2 to 5. Serum IgA constitutes 20% of the total serum immunoglobulin, and 80% of this is monomeric. The remainder exists as polymers, where n = 2 to 5. The other form of IgA is found in external secretions such as saliva, tracheobronchial secretions, colostrum, milk, and genitourinary secretions. Secretory IgA consists of four components: a dimer of two monomeric molecules, a 70-kDa secretory component that binds noncovalently to the IgA dimer, and the 15-kDa J chain that is believed to form a disulfide-bonded clasp at the C-terminus of the H chains (see Fig. 22-9). The isotype IgD has a molecular mass of 180 kDa. Its serum concentration is very low, approximately 3 mg/dL. IgD apparently functions as a membrane molecule, being associated on mature but unstimulated B cells in association with IgM. IgE is the homocytotropic or reaginic Ig and mediates immediate hypersensitivity. It has a molecular mass of 180 kDa and, similar to IgM, has four C domains. The Fc portion of IgE binds strongly to a receptor on mast cells, FcεR, and this is how this immunoglobulin exerts its particular activity. The overall properties of the immunoglobulins are summarized in Table 22-2.

Subclasses of isotypes IgG, IgA, and IgM have been identified. The structural basis for this antigenic heterogeneity is variation in amino acid sequence in the Fc portion of the H chain of a given class. The subclasses of human IgG, called IgG1, IgG2, IgG3, and IgG4, are the best characterized. Each has a slightly different structure, with the most notable differences being in the length of the hinge and in the number of interchain disulfide bonds (see Fig. 22-9 and Table 22-2). IgG1 constitutes 70% of the total IgG and IgG2 20%. IgG3 and IgG4 constitute 8% and 2%, respectively, of the total IgG. The subclasses of IgG exhibit different catabolic rates and bind differentially to cell-associated Fc receptors (FcγR) and to C1q. Specifically, IgG2 does not bind to the FcγRs and IgG4 binds about 10-fold less well than do IgG1 and IgG3. For C1q binding, the rank order of affinities is IgG3 > IgG1 > IgG2 » IgG4. Despite the most obvious sequence differences among the human IgG isotypes being in their hinge regions, studies using engineered domain-swapped chimeric molecules have demonstrated that it is the more subtle amino acid sequence differences within the respective Cγ2 domains that account for the differences in binding to C1q and to the FcγRs. Transport across the placenta is mediated by the Fc-neonatal receptor (FcRn) and for this functional activity IgG2 crosses the placenta slightly more slowly than the other three subclasses. The other known subclasses of Ig isotypes are associated with IgM (IgM1 and IgM2) and IgA (IgA1 and IgA2). The properties and function of these subclasses are less well known.

The second type of variation is called *allotypic variation*. It is attributable to genetically controlled antigenic determinants found on both the H and L chains. Although each human has all immunoglobulin isotypes, an individual has only one form of each allotype on his or her immunoglobulin molecules. Allotypes are codominantly expressed, but an individual B lymphocyte secretes only one of the parental forms. This phenomenon is called *allelic exclusion*.

The third type of variation is attributable to antigenic determinants that are unique to each particular antibody molecule produced by an individual. These markers are called *idiotypic determinants,* and they are associated with a single species of antibody. The antiidiotypic antibodies that recognize a particular idiotype will not react with any

Table 22-2 Human Immunoglobulins: Properties and Functions

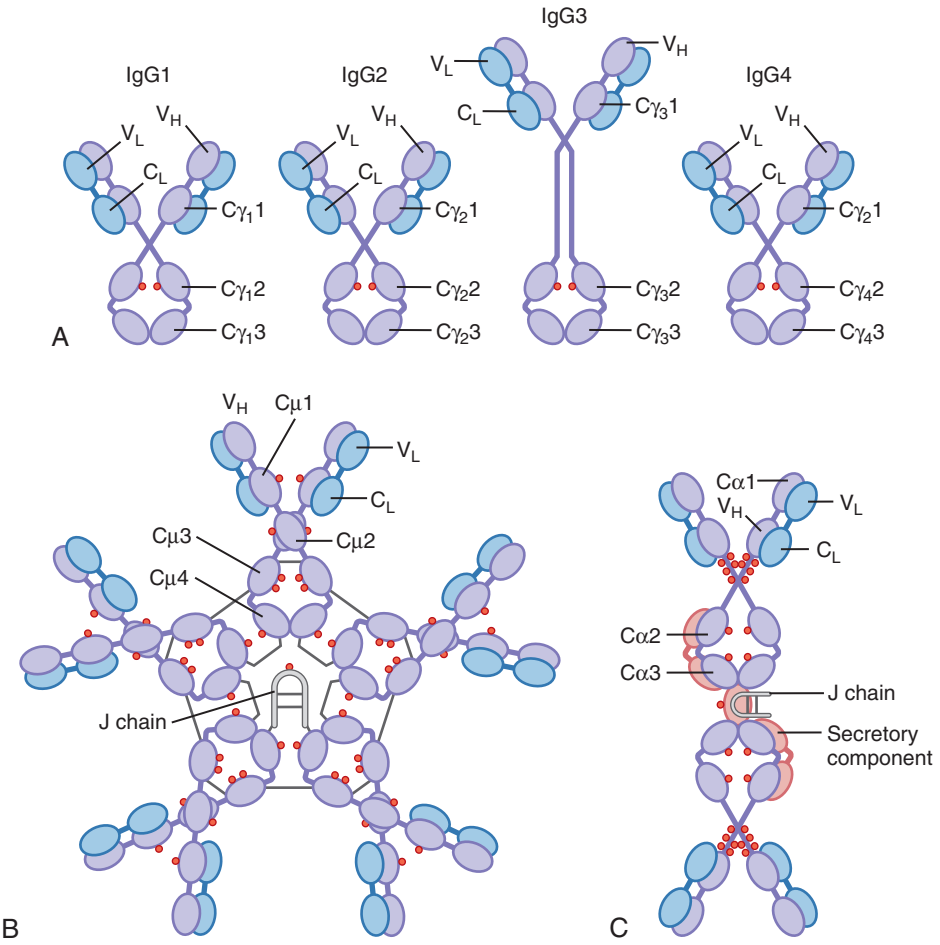

Figure 22-9 A, Structure of the four subclasses of human immunoglobulin G (IgG). Constant region domains are indicated by C_nN, where n is the subclass and N is the domain. **B,** Structure of human IgM. The J chain is shown in the model as disulfide linked to two μ-chains. Other models have been proposed. *Filled circles* indicate carbohydrate. **C,** Structure of human secretory IgA. This model shows the possible arrangement of the two IgA monomers in relation to the secretory component and J chain. As the IgA molecule passes through the epithelial cells, the secretory components are synthesized and attached covalently to the Fc domain of the α-chains that have previously been joined to the J chain with disulfide links. Light chains are shown in *blue,* heavy chains in *purple,* disulfide bonds as *gray lines,* and carbohydrates as *red circles*. *(From Turner M:* Molecules which recognize antigens. *In Roitt DK, editors:* Immunology*, London, 1989, Gower, p 51.)*

other immunoglobulins in the donor other than the purified antibody that was used to raise the antiidiotype antibody. In most cases, the immune response to an antigen results in a mixture of several antibodies, each of which has identical binding specificity but distinct idiotypic determinants. Thus, there can be many idiotypes for a given antigenic specificity, which has been interpreted as being a reflection of physical heterogeneity in or near the antibody combining site, for example, in the variable region domains. In some species (notably certain strains of mice), the response to antigen results in a predominant idiotype on all antibodies of a given specificity. Because this quality is inherited, the idiotypes are called major, cross-reactive, or public. Some public idiotypes have been found in certain species (again, most notably mice) to be genetically linked to allotypes. Three kinds of antiidiotype antibodies have been described, those that function as an internal image of the original antigen by mimicking the antigen structure, those that recognize antibody combining site-associated idiotypes, and those that are specific for framework-associated determinants. The internal image antiidiotypic antibodies are of clinical interest.

Every immunoglobulin is a glycoprotein, and the critical glycan is attached to the H chain in the Fc domain at the conserved asparagine at position 297 (Asn297). This single, N-linked glycan is essential for maintaining an open conformation of the two H chains as it lines the opposing faces of the pair of C_H2 subdomains of Fc (see Fig. 22-8, *B*). The core structure of the N-linked glycan is a biantennary heptapolysaccharide containing *N*-acetylglucosamine plus additional sugars (fucose, galactose), with bisecting *N*-acetylglucosamine and sialic acid variably present. Effector functions depend on the Asn297-linked glycan and are influenced by its structure.[142] Deglycosylated IgG does not interact effectively with Fcγ receptors (FcγRs) and cannot support in vivo effector responses, including antibody-dependent cell-mediated cytotoxicity or complement-dependent cytotoxicity.[143] Individual glycoforms contribute to modulating inflammatory responses and have disease association. For example, glycosylation differs in patients with rheumatoid arthritis[144] or vasculitis[145] compared with the normal population. Addition of sialic acid to the N-linked glycan reduces binding of IgG to FcγRs and reduces in vivo cytotoxicity. Regulation of sialylation of IgG contributes to the antiinflammatory homeostasis of serum IgG. Upon antigen challenge, reduced sialic acid–IgG can mediate immune clearance and protective immunity through interaction with subclass-specific FcγRs. Kaneko et al[146] have proposed that the protective effect of intravenous immunoglobulin (IVIg) therapy is attributable to the minor fraction of sialylated IgG species in the total IVIg

preparation and that the high doses required (1-3 g/kg body weight) for antiinflammatory activity could be significantly reduced by increasing the percentage of sialylated IgG.

Therapeutic Use

Immunoglobulin G was one of the first plasma proteins prepared in a purified state as a therapeutic drug for treatment of clinical disorders. It remains, along with albumin and α-proteinase inhibitor, the most widely used therapeutic plasma derivative and is currently the major plasma product on the global market. Polyvalent human immunoglobulin preparations have been used to reconstitute humoral immunity in agammaglobulinemic patients for more than 3 decades. Until 25 years ago, intramuscular treatment was the mode of administration. Intramuscular preparations caused severe adverse reactions when injected intravenously.[147-149] The most serious were anaphylactoid reactions and were probably complement mediated. Efforts to reduce anticomplementary activity and the prekallikrein activator activity were initiated in the early 1980s and safer IVIg preparations became available.

Intravenous immunoglobulin is prepared from pooled human plasma pools of 3000 to 50,000 L. The World Health Organization requires more than 1000 donors per lot. The majority of IVIg is produced by cold ethanol fractionation procedures,[150,151] with filtration and polishing chromatography steps added to increase yield and decrease pathogen transmission.[152,153] Gamunex (Talecris Biotherapeutics) is produced from cold ethanol fractionation followed by caprylate precipitation and chromatography.[152,154] This is the first significant change in commercial IVIg production in 20 years. IVIg contains concentrated IgG with normal plasma ratios of IgG1 and IgG2, lower percentages of IgG3 and IgG4, and only trace amounts of IgA and IgM. It retains the antibody repertoire, reflecting the combined immunologic experience of the donors.[155,156] Hyperimmune IVIg is purified from donor plasma selected for high titer toward a specific pathogen. Prophylaxis for cytomegalovirus and respiratory syncytial virus are two approved clinical applications.[156,157]

The availability of safe IVIg preparations and the fortuitous observation that IgG treatment of a patient with thrombocytopenia and IgG deficiency increased the patient's platelet count began an intense period of clinical use of IVIg for indications other than primary immune deficiency. In 1990, the National Institutes of Health sponsored a Consensus Development Conference, which produced the first consensus statement on IVIg clinical indications.[158] As a result, six disease indications—primary immunodeficiency, Kawasaki syndrome, chronic lymphocytic leukemia, human immunodeficiency virus (HIV) infections during childhood to prevent infections, BM transplantation to prevent graft-versus-host disease or bacterial infections in adults, and idiopathic purpura—were approved by the Food and Drug Administration (FDA) for labeling and marketing. The licensed indications remain unchanged, but off-label uses include more than 100 conditions (for further discussion, see Chapter 117).[159,160]

The experience with IVIg clinical development has been largely empirical and anecdotal. The mechanisms for patient benefit or harm are poorly understood, especially for high-dose immune modulation therapy. Various known and some yet undiscovered functions of immunoglobulins in immune homeostasis may contribute, including modulation of the function and expression of Fc receptors, interaction with complement and cytokine systems, antiidiotypic antibodies, and regulation of T-cell and B-cell function.[161-163]

Many effects of IVIg are explained by mechanisms beyond antigenic recognition of pathogens. IVIg preparations contain up to 30% dimers composed of idiotype–antiidiotype antibody pairs. These dimers appear to be very effective as a sink for activated complement and can inhibit complement activation.[164] Benefit for treatment of immune thrombocytopenia purpura seems to be mediated by Fc-receptor blockade of the reticuloendothelial cell salvage receptor, also known as FcRn, combined with an antiidiotypic neutralization of antiplatelet antibody that together eliminates antiplatelet antibody from the blood. Other indications of antibody neutralization can be seen in IVIg treatment of myasthenia gravis. The dramatic success of IVIg in treating Kawasaki syndrome may be attributable to several mechanisms, including antiidiotypic neutralization of antiendothelial antibodies, inhibition of cytokine production and function, and elimination of causative superantigens.[165,166] IVIg inhibits B-cell activation and autoantibody production by enhancing $CD8^+$ suppressor T-cell function. Cell-mediated immunity also is affected.[161] As mentioned earlier, Kaneko et al[146] ascribe much of the effect of IVIg to a small fraction of it which is sialylated. A 2011 report from this group suggests a mechanism for the way which sialylated IgG in IVIg downmodulates the inflammatory response of the immune system.[167] They suggest that the sialylated IgG Fc region binds to DC-SIGN, a molecule on the surface of "regulatory" myeloid cells, including DCs. In response to DC-SIGN ligation by sialylated IgG, these cells secrete the cytokine IL-33, which in turn stimulates IL-4 production by basophils. IL-4 upregulates the synthesis of the "inhibitory" class of FcγR on effector macrophages, namely FcγRIIB. Because ligation of this class of FcγR by immune complexes actually results in the recruitment of regulatory phosphatases, which shut down intracellular signaling cascades, the net effect is to increase the activation threshold required to initiate inflammation by these effector cells.

Adverse Events Related to Intravenous Immunoglobulin Infusion

Adverse events associated with IVIg can be characterized as (1) early systemic events, (2) infectious disease transfer, and (3) high-dose treatment-related adverse effects.[148]

Early Systemic Events

Common transfusion-related early events are listed in Table 22-3. Most early events are self-limiting and infusion rate dependent. Premedication with steroids, aspirin, or other nonsteroidal antiinflammatory drugs often decreases symptoms. Prophylaxis with propranolol can be effective for induced migraine. Aseptic meningitis is a rare early event, is observed 1 to 2 days postinfusion, is unrelated to infusion rate, and can be treated with intravenous steroids and analgesics.[148,168]

The frequency of reported adverse events varies considerably, ranging from 10% to 85%.[148,158,169-171] There are many reasons for this

Table 22-3 Early Systemic Adverse Events Associated With Intravenous Immunoglobulin Infusion

Fever	Rash or urticaria
Chills	Chest tightness
Sore throat	Dyspnea
Face flush	Wheezing
Tachycardia	Low or high blood pressure
Palpitations	Shock
Lumbar pain	Anxiety
Abdominal pain	Nervousness
Nausea	Headache
Vomiting	Migraine
Shaking	Anaphylaxis
Fatigue	Malaise
Myalgia	Leukopenia

high variability in reporting, including (1) differences in product,[153,169,172] (2) infusion rate, (3) dose and frequency of dosing, (4) patient population, and (5) relative experience of patient and physician. Both patients and physicians become steeled to the adverse events, and because incidents are not life threatening and often respond to prophylaxis medication, they are ignored as "normal." Nonetheless, these events are common and affect health and quality of life of patients.[159,169]

Infectious Disease Transfer

A few early preparations of IVIg transmitted hepatitis C virus. Manufacturers have added viral inactivation and partitioning steps, and current licensed products are safe with respect to HIV, hepatitis C virus, hepatitis B virus, and other bloodborne pathogens (see Chapter 117).[173] The industry has responded to the threat of prions with process validation,[170,174] donor screening, donor testing, inventory management (look back), and plasma pool testing.

High-Dose Treatment-Related Adverse Events

Intravenous immunoglobulin treatment for immune modulation of neurologic diseases requires doses of 1 to 2 kg/kg body weight or two to five times the dose recommended for replacement therapy. Adverse events with high-dose administration include those listed in Table 22-3 and occasionally thromboembolic events, renal complications, and anemia.[148,171,175-178] Thromboembolic events include deep venous thrombosis, pulmonary embolism, myocardial infarction, and stroke. Thromboembolic events and renal failure seem to be independent of infusion rate. The cause of thromboembolic events is not known. Dalakas[179] has suggested that increased serum viscosity plays a role. Factor XIa has also been identified in IVIg preparations.[172] Factor XIa could directly lead to shortening of coagulation time and risk of thrombosis. Renal complications are rare but result in high morbidity and mortality. Whether IgG, contaminants, or excipients are responsible is not clear. Of the 88 renal adverse events reported to the FDA, 90% were stabilized with sucrose.[148,168] Whether the adverse events observed with IVIg treatment of neurologic diseases are related to a preexisting medical condition or the high doses required for treatment is not clear.

Monoclonal Antibody Therapy

Monoclonal antibody technology as described in 1975 by Kohler and Milstein[180] is now well established for the production of diagnostic and therapeutic mAb. Despite early enthusiasm and much research and development effort, the development of clinical mAb was frustrated for 20 years by reports of severe toxicity and poor clinical efficacy. Only one mAb, OKT3, an anti-CD3, was licensed for clinical use before 1994. Over the past 15 years, the situation has changed. mAb products constitute as much as 25% of new biologicals in clinical development, with a first in humans to regulatory approval success rate of 27%, which compares very favorably with the 11% rate for small-molecule drugs.[181,182] Table 22-4 lists the more than 22 mAbs that have received FDA approval as of early 2009.

The list includes antibodies for diverse clinical conditions, including oncology, chronic inflammatory conditions, solid organ transplantation, infectious disease, and cardiovascular medicine. Approved antibody therapy includes unmodified mAb, radioimmunoconjugates, immunodrug conjugates, and antibody fragments. More than 150 mAbs are in clinical development, with at least 33 in clinical trials for conditions, including colorectal cancer, melanoma, postmenopausal osteoporosis, cutaneous T-cell lymphoma, rheumatoid arthritis, and respiratory syncytial virus infection.[182] Part of the progress is attributable to the advent of genetic engineering, which has allowed the production of "humanized" mAbs. Human–mouse chimerized Ab with limited mouse determinants or fully human mAb now are produced by DNA technology or with transgenic mice. The humanization of mAbs provides some protection from the patient's immune system, prolonging the circulation half-life from less than 24 hours for murine mAbs in humans and approaching the 21-day half-life of native IgG. Increased circulation time is partly attributable to the reduction in immune reactivity and subsequent opsonization of mAbs but also because human but not murine IgG is recycled by FcRn on human epithelial cells.[183,184]

ReoPro (abciximab) is a chimeric Fab fragment directed to glycoprotein IIb/IIIa and is one of the early successful clinical mAbs (approved for marketing in 1994). ReoPro prevents thrombus formation in patients undergoing procedures such as percutaneous coronary intervention.[185] Another example of a chimeric mAb (IgG1) is Remicade (infliximab), which is an anti–TNF-α. Remicade was approved in 1998 for treatment of Crohn disease and in 1999 for treatment of rheumatoid arthritis.[186,187]

Monoclonal antibodies for cancer therapy are divided into two stratagems. "Naked" mAbs target specific tumor-related antigens or cell receptors to recruit the immune system or to modify the growth of tumor cells. Examples of approved naked mAbs are Rituxan (rituximab),[188] an anti-CD20 approved for non-Hodgkin lymphoma, and Herceptin (trastuzumab),[189] an anti-HER2 approved for advanced breast cancer. To date, most naked mAb candidates have been disappointing, and the most efficacious are used as adjuvant therapy. The most promising naked mAbs may not directly affect the tumor cell but instead may modify the patient's immune response to the tumor. An example of immune-modulating mAbs in development is anti-CD152,[190] which may modulate the way T cells respond to cancer cells.

The second strategy is to attach or conjugate an antitumor agent to an antitumor mAb. The mAbs deliver the toxic agent to the tumor or tumor cells in an attempt to obliterate the cancer cells. Both radioactive and chemical toxins have been conjugated to a variety of tumor-specific mAbs. Two mAbs that deliver radioactivity directly to the tumor are Zevalin (ibritumomab tiuxetan) and Bexxar (tositumomab), which were approved in 2002 and 2003, respectively, for B-cell non-Hodgkin lymphoma.[191,192] Many immunotoxins have been developed but without much clinical success. Mylotarg (gemtuzumab ozogamicin), an anti-CD33 mAb, is approved for myelogenous leukemia when chemotherapy is not effective or appropriate.[193]

A listing of approved mAb therapy for cancer can be found online on the American Cancer Society's web page (at www.cancer.org) under Monoclonal Antibody Therapy (Passive Immunotherapy). For a review of therapeutic MAbs, see Carter.[194]

Finally, the humanized anti-C5 mAb Soliris (eculizumab) provides an interesting tie-together between the complement section of this chapter and the present section on therapeutic monoclonal antibodies. Soliris binds to C5 in a way that prevents its cleavage by C5 convertases of either the classical or APs. As such, it not only blocks the generation of C5a, the most powerful of the complement inflammatory agents, but also prevents formation of the MAC. At the same time, its activity does not grossly impair the opsonic function of complement against most pathogenic microorganisms, the exception being *N. meningitidis,* whose clearance depends on the activity of the lytic complement pathway. Fortunately, there is a vaccine for this microorganism that can be administered prophylactically before commencement of treatment with Soliris. In 2007, Soliris received FDA approval for treatment of paroxysmal nocturnal hemoglobinuria (PNH), a very rare complement-mediated hemolytic disease resulting from the absence of the MAC regulator CD59 on all host cells, particularly on erythrocytes, which, unlike nucleated host cells, have no way of repairing a MAC-generated membrane lesion. Biweekly administered Soliris has proven to be extremely effective in keeping PNH patients symptom free.[195] In addition to treatment of PNH, beginning in 2009, there have been an ever-increasing number of case reports in the literature in which Soliris is being used off-label for the effective management of aHUS, which as discussed earlier, is a disease caused by dysregulation of the alternative complement pathway.[196] The problem, however, is cost, being approximately $400,000 per year because of the very high development and manufacturing costs, contrasted with a very small market owing to the rarity of both PNH and aHUS. AMD is another AP dysregulation disease that in a mouse model of the wet form of human AMD, has been shown to be C5-,

Table 22-4 Monoclonal Antibodies Approved by the Food and Drug Administration for Therapeutic Use*

Trade Name	Company	Target	Source	Year	Indication
Orthoclone	Ortho Biotech, Inc. (subsidiary of J&J)	CD3	All rodent	1986	Transplantation rejection
ReoPro	Centocor, Inc. (subsidiary of Johnson & Johnson) and Eli Lilly	GPIIb/IIIa	Chimeric	1994	High risk angioplasty
Rituxan	Biogen Idec and Genentech, Inc.	CD20	Chimeric	1994	Non-Hodgkin lymphoma, rheumatoid arthritis

Simulect	Novartis	CD25	Chimeric	1998	Transplantation rejection
Synagis	Medimmune	RSV F protein	Humanized	1998	RSV infection
Zenapax	Hoffmann-La Roche Inc., Protein Design Labs	CD25	Humanized	1997	Transplantation rejection
Herceptin	Genentech	HER-2	Humanized	1998	Breast cancer
Mylotarg	UCB and Wyeth	CD33	Humanized	2000	Acute myeloid leukemia
Campath	Millenium Pharmaceuticals, Inc. and Berlex Laboratories, Inc.	CD52	Humanized	2001	Chronic lymphotic leukemia, T-cell lymphoma
Zevalin	Idec Pharmaceuticals Corporation	CD20	Murine with yttrium90 or indium-111	2002	Non-Hodgkin lymphoma
HUMIRA	Abbott Laboratories/Cambridge Antibody Technology	TNF-α	Human	2002	Inflammatory diseases—mostly autoimmune disorders such as rheumatoid arthritis, psoriadic arthritis, Crohn disease
Bexxar	Corixa Corp. and GlaxoSmithKline	CD20	Murine covalently bound to iodine-131	2003	Non-Hodgkin lymphoma
Xolair	Genentech, Tanox, Inc., Novartis Pharmaceuticals	IgE	Humanized	2003	Severe (allergic) asthma
Avastin	Genentech	VEGF	Humanized	2004	Metastatic colorectal cancer, non–small cell lung cancer, metastatic breast cancer
TYSABRI	Biogen Idec and Elan Corp.	α4 subunit of α4β1	Humanized	2004	Multiple sclerosis, Chron disease
Erbitux	Merck KG aA/Bristol-Myers Squibb/ ImClone Systems	EGFR	Chimeric	2004	Colorectal cancer, head and neck cancer
Vectibix	Amgen	EGFR	Human	2006	Metastatic colorectal carcinoma
LUCENTIS	Genentech	VEGFA	Humanized Fab	2006	Wet macular degeneration
Soliris	Alexion Pharmaceuticals, Inc.	C5	Humanized	2007	Paroxysmal nocturnal hemoglobinuria
CIMZIA	UCB	TNF-α	Humanized (Fab)	2008	Crohn disease, rheumatoid arthritis
Simponi	Centocor (subsidiary of Johnson & Johnson)	TNF-α	Human	2009	Rheumatoid and psoriatic arthritis, active ankylosing spondylitis

From http://www.actip.org/pages/library/Table_Monoclonal_Antibodies.pdf.
EGFR, Epidermal growth factor receptor; *GP*, glycoprotein; *HER-2*, human epidermal growth factor receptor 2; *RSV*, respiratory syncytial virus; *TNF*, tumor necrosis factor; *VEGF*, vascular endothelial growth factor.
*In total, 22 monoclonal antibodies were approved by the U.S. Food and Drug Administration for therapeutic use as of early 2009. The table gives a chronologic listing.

and indeed MAC-dependent.[197] Unlike PNH and aHUS, AMD is not a rare disease, and thus if Soliris were to be an effective therapeutic, the cost of the treatment would likely drop to the range of other monoclonal antibodies needed for continuous therapy (~$40,000-$100,000 per year). Very recently, a patient enrolled in a clinical trial of Soliris use for a neurologic condition, who also happened to have symptoms of the wet form of AMD (i.e., macular edema and widespread exudates), was found to have a significant improvement in his vision, as well as resolution of his exudates, shortly after the commencement of the treatment with Soliris.[198] This observation is encouraging but of course needs to be confirmed in a proper clinical trial.

CHAPTER 23

TOLERANCE AND AUTOIMMUNITY

Mark J. Shlomchik

The immune system must balance the capacity to respond to foreign antigens and the need not to respond to self-antigens. A complex and multilayered approach has evolved to successfully handle this problem. However, autoimmune diseases, in which this balance is upset, are remarkably common in the population. The diversity and variable severity of such diseases most likely reflects the various approaches the immune system takes to regulate antiself responses and thereby the various points at which this multilayered system can break down. The normal functions that may prevent autoimmune disease are collectively known as *self-tolerance mechanisms*.

Autoimmune diseases are relevant to hematology at several levels. Autoimmune hemolytic anemia (AIHA) and idiopathic thrombocytopenic purpura are syndromes in which spontaneous autoimmunity to formed blood components may require transfusion support that is rendered difficult because of the presence of autoantibodies. Some cases of aplastic anemia may also fall into this category. Autoantibodies to red blood cells (RBCs), whether pathogenic or not, are often problematic in terms of typing and screening. Another class of diseases are those induced by transfusion but that are nonetheless autoimmune in nature: these include posttransfusion purpura (PTP)[1-3] and possibly AIHA associated with transfused thallasemia.[4-6] Finally, graft-versus-host disease (GVHD), a common complication of allogeneic stem cell transplantation, although not a classical autoimmune disease, shares many features of autoimmune syndromes.[7,8]

An important principle in understanding the etiology of autoimmune diseases is that no special mechanisms, cells, antibody types, or reactions are specific to autoimmune diseases. Rather, the pathogenesis involves the inappropriate or dysregulated triggering of the normal mechanisms of immunity. Therefore, an understanding of autoimmune disease induction and pathogenesis requires a grounding in the basic immune cell functions and interactions, which can be found in the preceding chapters.

SELF-REACTIVE LYMPHOCYTES: ORIGIN AND CONTROL

Origins

Inevitably, autoreactive lymphocytes are generated as a consequence of the fact that B-cell receptor (BCR) and T-cell receptor (TCR) genes are encoded in pieces that rearrange in the DNA of precursor lymphocytes to ultimately form a complete gene. This process allows for many possible gene segment combinations (e.g., 4000 different ones for the human Ig heavy chain alone), and in addition, small deletions and random additions at the sites where the pieces are joined together create additional diversity. There are two implications of this process for self-tolerance. First, it is impossible to prevent the assembly of a self-reactive receptor by filtering these out of the germline gene repertoire. Second, a developing lymphocyte cannot be considered autoreactive until the assembly process is complete and the BCR or TCR is expressed. Thus, autoreactive lymphocytes are produced every day, and it is at this key developmental stage—when the BCR or TCR is first expressed by the cell—that the immune system can first eliminate these potentially harmful cells. For B cells, this occurs in the bone marrow (BM), the primary central lymphoid organ (Fig. 23-1); for T cells, it occurs in the thymus. The process is thus termed *central tolerance*.

Regulation: Central Tolerance

Clonal Deletion

The classical experiments of Pike and Nossal were the first to demonstrate that developing autoreactive B cells can be eliminated in the BM.[9-11] The details of this process remained murky until the Goodnow and Nemazee groups each developed a BCR transgenic mouse system for the study of self-tolerance.[12-14] These mice have been genetically altered to carry the preformed immunoglobulin (Ig) variable (V) genes that encode a specific autoantibody. Mice that have undergone this genetic transfer are termed *transgenic,* and the gene that is transferred is termed the *transgene* (Fig. 23-2). The presence of this preformed transgene short circuits and prevents the normal rearrangement process at the natural Ig gene loci. Thus, each B cell in the animal expresses only the transgene and has the same specificity. By choosing a target antigen that is carried by only some strains of mice (e.g., the polymorphic major histocompatibility complex class I genes used by Nemazee), it is possible to render the transgenic B cells autoreactive when crossed onto one strain (Fig. 23-3) but not autoreactive in a different strain. The results of such systems were dramatic. A complete loss or deletion of the B cells was demonstrated in the strain of mice that had the autoantigen, but perfectly good expression of the B cells was observed when the autoantigen was absent. This provided clear proof of B-cell clonal deletion. Furthermore, it was shown that this deletion occurred at the immature B-cell stage, just when the cells first express their BCR.[15-17] It has been since discovered that deletion is just the final step in controlling autoreactive B cells.[15,17-19] B cells that have completed H- and L-chain rearrangement and then recognize self-antigen while still immature in the BM may actually undergo a second round of V gene rearrangement. This most likely occurs at the L-chain loci, which are particularly suited to secondary V to J rearrangements. This process has been termed *receptor editing*. Evidently, a cell has a certain period of time in which to produce a second L-chain rearrangement that will inactivate the cell's self-reactivity. If this does not occur, the cell fails to mature and is eventually eliminated. The physiologic role of the editing process is still unclear, but it could represent a way to maximize the efficiency of B-cell generation while still maintaining an effective filter against strongly self-reactive B cells.

More recently, evidence has been accumulating that autoreactive B cells are similarly filtered out of the human repertoire. Polyreactive and antinuclear B cells are progressively eliminated during the progression of B-cell development; however, even in healthy individuals, some B cells with detectable autoreactivity remain among mature B cells.[20]

Clonal Anergy

Another type of self-tolerance mechanism was also revealed by similar experiments in mice. This form, clonal anergy, involves inactivation of the self-reactive cell but not its elimination.[10,14] Such B cells remain in the peripheral lymphoid circulation, albeit with a shorter lifespan than normal B cells. In addition, these cells have a lower amount of

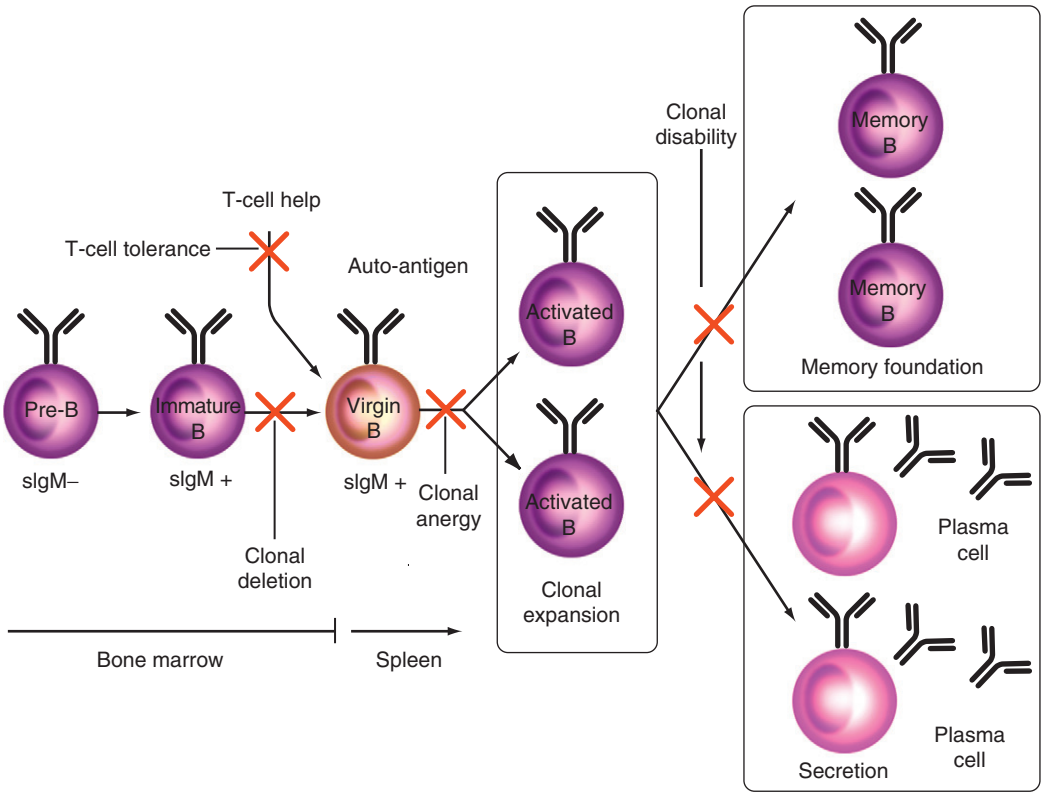

Figure 23-1 STAGES AT WHICH SELF-TOLERANCE CAN BLOCK B-CELL DEVELOPMENT. *Arrows* indicate the normal pathway of development. *X* indicates where these differentiation steps can be interrupted for self-reactive B cells as a consequence of encountering self-antigen. Each X is labeled with the type of self-tolerance it represents. The clonal disability steps are somewhat more hypothetical than the earlier steps. See text for details. *sIgM*, Surface immunoglobulin M.

surface Ig (sIg) and, moreover, are much less capable of sensing the presence of antigen when the sIg receptor is triggered. This second form of B-cell tolerance, demonstrated dramatically through the use of Ig transgenic mice, was also anticipated in the experiments of Pike and Nossal.[10] The physiologic advantage of maintaining these anergic cells is unclear. They can be activated by strong stimulation under certain conditions; thus, it has been suggested that they are maintained as a secondary repertoire to maintain greater B-cell diversity and thus better protect against a broader spectrum of pathogens. However, the presence of these cells also raises a danger that they may be activated by self-antigens as well, which could represent a source of autoantibodies. Indeed, it has been suggested that autoantibody-secreting B cells can arise by the activation of anergic B cells.

Clonal deletion, receptor editing, and clonal anergy are often referred to as "central" self-tolerance because they can occur in the central lymphopoietic organs and act on immature lymphocytes that have just expressed their antigen receptors. Central tolerance is probably most important in purging or controlling very high-affinity antiself lymphocytes.

Tolerance of Memory B Cells

Fig. 23-1 indicates that there are yet other stages of B-cell development at which one could imagine that self-tolerance should occur. The most important of these is development of memory B cells, the long-lasting cells that harbor the ability of the immune system to respond better and faster to antigens that have already been encountered once. An important and unique process occurs during memory cell development—the genes that encode the antibody receptor molecule undergo a process of random mutation.[21-23] This process is thought to provide mutants with an increased affinity for the immunizing antigen, and in fact, the secondary immune response is known to be of higher affinity. However, a side effect of any random process, just as in the receptor rearrangement itself, is the potential to create novel antiself specificities.[24,25] Thus, many have postulated that there should be a screening of cells for self-reactivity during memory B-cell development.[26-28] In fact, some evidence suggests this process exists, but it is much more elusive than clonal deletion or clonal anergy. Moreover, some new evidence indicates that the normal human IgG memory B-cell compartment does contain autoreactive B cells that nonetheless do not normally cause disease.[29]

T Cells

In many respects, self-tolerance for T cells is similar to that for B cells; both deletion and anergy exist.[30-34] The principle differences reflect the basic differences in B- and T-cell development. Deletion for T cells occurs in the thymus (where TCR gene rearrangement occurs), not in the BM. In addition, the self-antigens for T cells consist of self-peptides, just as the foreign antigens for T cells are foreign peptides. One key implication of these differences is that it may be difficult to tolerize developing T cells to peptides derived from proteins that are not expressed in the thymus. Over the past 10 years, data have emerged supporting the concept that many peripheral tissue proteins are "ectopically" expressed in the thymus, presumably to promote self-tolerance. These self-proteins are expressed in specialized thymic epithelial cells concentrated in the thymic medulla. Strikingly, a gene known as Aire (autoimmune regulator) was found to be required for the expression of a large number of these peripheral tissue proteins. This gene is nonfunctional in humans with the autoimmune polyglandular syndrome-type I (APS-1, also known as APECED); people with the condition have autoimmune-based failure of multiple endocrine organs as well as autoimmunity in a variety of target tissues

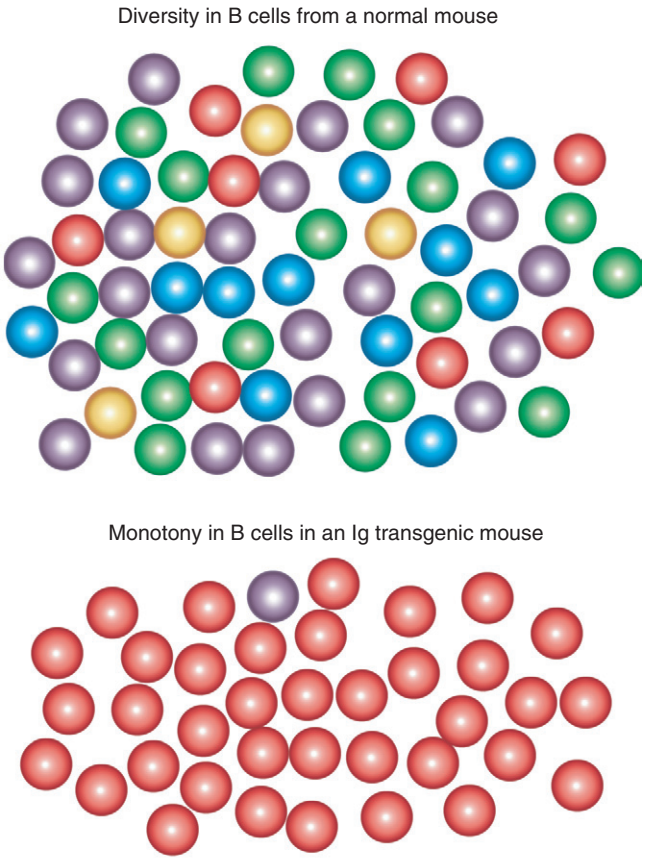

Figure 23-2 CLONAL DIVERSITY IN A NORMAL VERSUS TRANSGENIC MOUSE. The great diversity of B-cell specificities found in a normal mouse is indicated by the different patterns in each type of B cell. In contrast, in a transgenic mouse, each B cell expresses the same specificity because each carries the genes for a preformed heavy- and light-chain immunoglobulin (Ig) gene (the transgenes). This is indicated by the same pattern in each B cell. The one B cell with a different pattern signifies that occasional cells will express a unique specificity even in a transgenic because the system is imperfect.

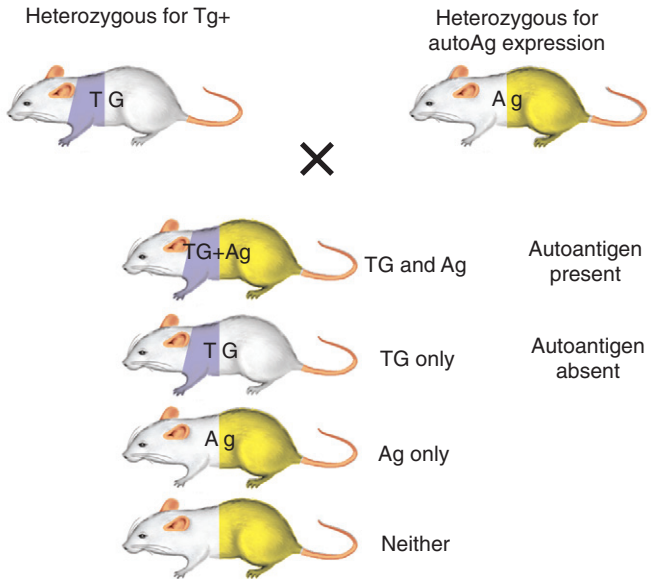

Figure 23-3 MATING STRATEGY TO GENERATE TRANSGENIC (TG) MICE WITH AND WITHOUT A POLYMORPHIC AUTOANTIGEN (Ag). Two mice are crossed, each of which is heterozygous, one for the transgene and the other for a polymorphic autoantigen (much as people can be heterozygous for blood group antigens). Shown are the possible resulting progeny of such a cross, each of which would occur at one-fourth frequency. The first two types of mice, one with TG and Ag and the other control with TG and not the Ag, are compared in experiments to determine how autoantigen affects the development of the autoreactive B cells.

such as the stomach. Mice with an induced mutation on Aire have a similar phenotype. Hence, specific mechanisms enhance thymic T-cell tolerance to otherwise sequestered peripheral antigens.[35]

Limitations of Central Tolerance

Although these mechanisms to eliminate or inactivate self-reactive B cells as they first emerge are clearly critical for the viability of an animal, they only account for part of the overall system that protects against autoimmunity. There are many reasons to believe that central tolerance cannot and should not be perfectly efficient. One is that the ability to tolerate self must be balanced against the ability to efficiently respond to a wide variety of foreign antigens. Each cell that is eliminated in the interests of self-tolerance is one that cannot respond to a potential foreign antigen. This concept is illustrated metaphorically in Fig. 23-4. Thus, one must suppose that it might be advantageous to allow some (weakly) antiself cells to escape these purging mechanisms. This is indeed the case. A second way to view this same problem is that even if it were desirable to have complete elimination of antiself lymphocytes, it would be impossible. It is unlikely that during development, each cell will be exposed to a sufficient quantity of each and every self-antigen in the body to be functionally tested for self-reactivity. Furthermore, some antigens are tissue specific, such as thyroglobulin, and are unlikely to be found in the circulation at appreciable quantities.

Persistence of Self-Reactive Lymphocytes

Thus, despite central tolerance, self-reactive cells nonetheless exist in peripheral lymphoid organs of normal animals. It has been observed for some time that many immune responses are accompanied by transient antiself antibody responses.[36-40] For example, rheumatoid factors with specificity for self-IgG often accompany strong secondary immune responses to foreign proteins or viruses.[36-38] The simplest explanation for such phenomena is that the B cells that make these autoantibodies already exist in the peripheral lymphoid compartment but are quiescent until they receive the proper stimulus. (How such cells get activated and why in normal animals this does not pose a threat are discussed following.)

Transgenic mouse models similar to those described above have provided the most convincing evidence of the existence of such B cells. One of particular relevance to hematology was generated by Honjo et al[41] These workers isolated the V genes that came from an actual anti-RBC autoantibody originally obtained from an NZB mouse with AIHA. Similar to Goodnow and Nemazee, they used the transgenic approach to express the anti-RBC antibody in a normal nonautoimmune mouse. Although central deletion was seen in most of the transgenic mice studied, many also had some residual autoreactive B cells in the spleen and lymph nodes, and some otherwise normal mice even developed frank AIHA. These results were interpreted as follows: central tolerance is not completely efficient even in a nonautoimmune mouse, and some autoreactive B cells can be stimulated to cause disease. Shlomchik et al, also using a transgenic approach, demonstrated that a rheumatoid factor autoantibody that was isolated from a diseased mouse was not subject to self-tolerance when expressed in a normal BALB/c mouse.[42] These B cells generally remained quiescent in a normal animal, suggesting that B cells that are not usually regulated by self-tolerance (perhaps because they recognize the self-antigen only weakly) may be the precursors of pathogenic autoantibodies in disease.

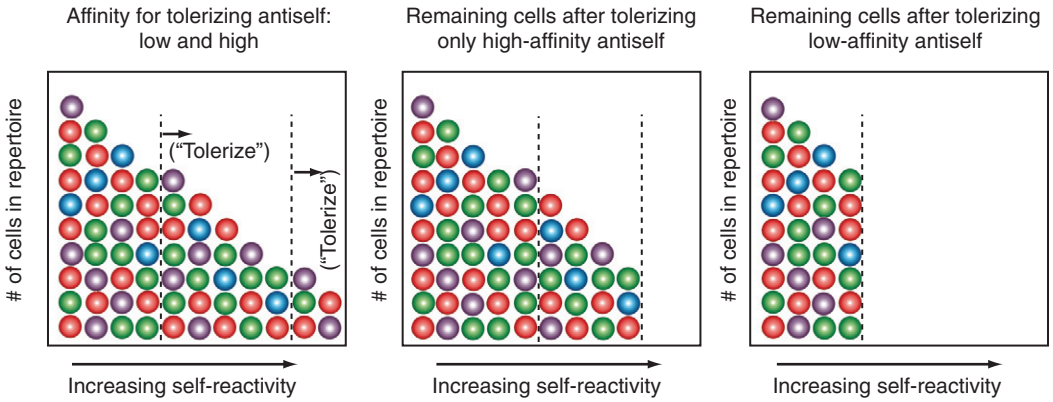

Figure 23-4 HOW ELIMINATION OF AUTOREACTIVE CELLS AFFECTS THE REPERTOIRE OF LYMPHOCYTES CAPABLE OF RESPONDING TO FOREIGN ANTIGENS. A hypothetical population of diverse B cells representing the entire repertoire available to respond to foreign antigen is depicted. The population is arrayed according to increasing self-reactivity *(left panel)*. Tolerizing only the high-affinity antiself B cells *(middle panel)* leaves most of the potential repertoire intact. However, as the affinity cutoff for self-reactivity increases, fewer B cells will be included. It can be readily seen *(right panel)* that a low threshold for inactivation or deletion of self-reactive cells will lead to a small number of competent residual cells available for responses to foreign antigens. Thus, a stringent tolerization of low affinity antiself cells will compromise the ability to respond to nonself.

Control of Self-Reactive Lymphocytes: Preventing Activation

The recognition that potentially self-reactive lymphocytes exist in the peripheral lymphoid repertoire of normal individuals,[43] despite central tolerance, raises the question of why they do not usually cause disease. One reason is the second layer of immune tolerance that prevents activation of self-reactive lymphocytes that exist in the periphery. This layer consists of several facets, which are described in the following sections.

Absence of Self-Antigen

The simplest explanation for why a self-specific lymphocyte is not spontaneously activated in the peripheral lymphoid compartment is the absence of self-antigen. This may be the reason why it was not eliminated in the first place. This situation has been termed clonal ignorance. It is related to the scenario described for rheumatoid factor B cells above in that the cell does not seem to care about the concentration of its autoantigen. In the case of rheumatoid factor, though, this is because the cell has relatively low affinity for self-IgG; in the case of thyroglobulin, for example, this is because the antigen concentration is vanishingly small. However, a change in antigen concentration, such as after thyroid damage from a viral infection, might then precipitate activation of these heretofore ignorant cells, leading to autoimmunity.

This antigen sequestration concept only applies to a limited set of autoantigens. A more general reason that self-specific lymphocytes remain quiescent, despite the ubiquity of self-antigens, is that for the vast majority of self-antigens, T and B cells are dependent on each other for activation (see Chapter 18).[44-47] It is evident that for this to occur, B and T cells specific for the same self-antigen must be in the same place at the same time. If such cells are rare, then the requisite coexistence of two such cells will happen very infrequently, minimizing the chance of starting an autoimmune reaction. A second consequence of T–B interdependence is that specific inefficiencies of central tolerance in one limb can be compensated for in the other. For example, T cells are probably very efficiently purged of cells that react with thymus-specific antigens, but B cells are probably not. However, antithymus B-cell responses are unlikely even though many thymus-specific B cells probably circulate; the cognate T cell with specificity for the same self-antigen simply does not exist.

Costimulation

Even when a B cell and a T cell that do recognize the same self-antigen encounter each other, the result may still not be activation. This is because a positive response by a lymphocyte to antigen encounter also requires a second signal aside from the stimulus of antigen recognition itself. These signals are transmitted through a series of ligand–receptor molecular pairs known as costimulatory molecules (see Chapter 19). The most important of these are: CD80 and CD86[48-53]1 (expressed on B cells, macrophages, and dendritic cells) and CD28[52,53] (expressed on T cells). Another important pair is CD40[54,55] (expressed on B cells, macrophages, and dendritic cells) and CD40 ligand[56-61] (CD40L, expressed on T cells and missing in patients with X-linked immunodeficiency/hyper-IgM syndrome[63-65]). CD40 stimulation is especially important for B cells, as it is for other antigen-presenting cells (APCs) as well. Other significant costimulatory molecules in T–B interactions include ICOS and ICOS-L (not shown in the figure), which are critical for germinal center responses and isotype switching.[66] Also in this category are lymphokine signals. For B cells, interleukin-4 (IL-4) signaling is important, but other cytokines such as IL-2, IL-5, IL-6, IL-21 also play roles in growth and differentiation. As shown in Fig. 23-5, some of these molecules are constitutively expressed, but others are induced in activated cells. This pattern of expression and induction leads to a cascade of events that occur during immune activation.

In general, for proper transmission of this second signal, one or the other of the lymphocytes must have been previously activated. This concept generates a paradox in that if one lymphocyte must already be activated, how is it possible to start an immune response at all? This is resolved in several ways. First, it is indeed difficult to start immune responses, and this is one of the mechanisms by which nonresponsiveness to self is maintained. However, a strong or prolonged first signal to a T or B cell may be sufficient for it to induce its costimulatory molecules.[48,67] Second, inflammation of any type is a powerful nonspecific inducer of these same costimulatory molecules.[68-70] Thus, in the presence of ongoing inflammation, such as would occur with infection or trauma, immune responses are much easier to start. Indeed, recent evidence suggests an important role in systemic autoimmunity for Toll-like receptors (TLRs), which recognize molecules specific to pathogens and induce costimulatory molecules and immune system activation. Ligands for TLRs include lipopolysaccharide (TLR4), bacterial DNA enriched for CpG dinucleotides (TLR9), and ss and dsRNA (TLR7 and TLR3). TLRs can

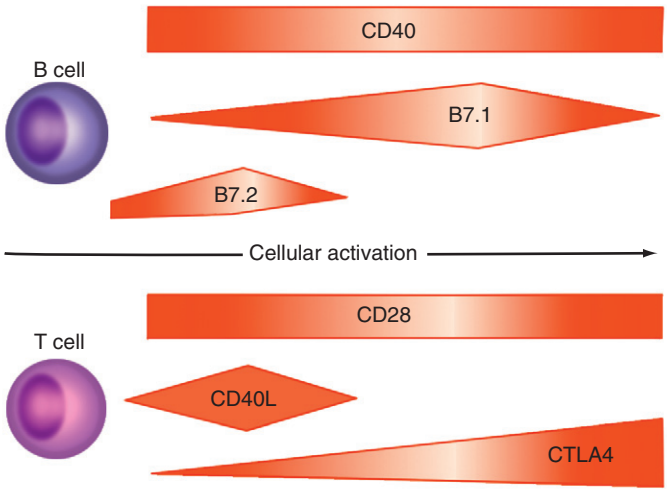

Figure 23-5 TIMING OF EXPRESSION OF COSTIMULATORY MOLECULES. The schematic shows the regulated expression of the CD40–CD40 L family *(light red)* and the B7-CD28–CTLA4 family *(dark red)* of molecules. From left to right is depicted increasing cellular activation as time elapses after initial encounter with antigen. The expression level of each molecule over time is indicated by a *polygonal shape*. The vertical width of the shape at any time reflects the degree of expression at that time. For example, CTLA4 is expressed little at the start and the expression increases continuously over time. The shapes depicting expression of molecules that are thought to deliver signals are outlined in ***bold,*** and those of molecules thought to receive signals are in *fine line*. The top three molecules are chiefly expressed on B cells and the lower three on T cells.

be activated by infection and may provide a mechanism by which some infections can trigger autoimmunity. However, in the right context some self (as opposed to pathogen) molecules, such as DNA found in chromatin, a target for systemic lupus erythematosus (SLE) autoantibodies, can also activate TLRs (TLR9 in the case of DNA).[71] Third, certain "professional" APCs, such as dendritic cells, may constitutively express these costimulatory molecules at moderate levels and can start the cascade, for example, by activating T cells, which is then amplified by T–B interactions.[70] In summary, there are two main functions of costimulatory requirements: (1) they focus the interactions between two antigen-specific T and B cells and limit nonspecific interactions, and (2) they restrict immune responses in the absence of inflammation. Both of these features of costimulation tend to prevent the activation of self-reactive lymphocytes that exist in peripheral lymphoid organs. For B cells, this means that tolerance in the T-cell compartment alone will prevent many self-reactive B cells from being activated.

Even with antigen sequestration and costimulatory regulation, mechanisms that prevent the activation of self-reactive lymphocytes are incomplete at best. For example, it seems likely during infection or trauma that antiself responses could initiate because costimulatory molecules will be nonspecifically induced. Indeed, this is the case. Furthermore, during infection and tissue damage, self-proteins that ordinarily are sequestered can be released. This leads to activation of the ignorant cells circulating in the body.[72-77] In fact, (usually) self-limited autoimmune responses after infection are well known, such as poststreptococcal glomerulonephritis or postmycoplasmal cold agglutinins. Although these syndromes can cause serious clinical problems, they are self-limited, unlike autoimmune diseases such as SLE.

Control of Self-Reactive Lymphocytes: Downregulation

The difference between transient autoimmune responses and chronic severe autoimmunity may lie in the third layer of protection against autoimmunity: downregulation of ongoing responses. Again, this layer is a normal part of the immune system, functioning to regulate both normal and autoimmune responses. Initially, in a normal response to a viral pathogen, there is great proliferation of lymphocytes specific for viral antigens. This process leads ultimately to the elimination of the pathogen, which was traditionally thought of as the signal to stop an immune response. However, when the pathogen is eliminated, in the absence of any other regulatory mechanism, there would be many residual cells that had been responding to the pathogen. Although a few such cells could be retained to provide immunologic memory, most of these are no longer useful in the short term. In addition to unnecessarily filling the lymphoid compartment, these cells may be a risk for causing autoimmunity. This is because of the possibility of the generation of newly autoreactive B cells by virtue of random somatic mutation.[25] B cells responding to foreign antigens begin to mutate their antibody V region genes. Mutation is a random process, and thus a mutation could occur that converts a nonautoimmune B cell into a self-reactive B cell.[25] No clear mechanism exists by which the body can discriminate and specifically eliminate these newly self-reactive mutant B cells. However, at a minimum, elimination of most of the reactive B cells regardless of specificity would mitigate this problem.

Over the past several years, several pathways for the removal of such postexpansion cells have been elucidated. One seems to be an inborn program that causes cells to apoptose after undergoing a certain amount of proliferation.[78-80] Particularly important in this program in lymphocytes are the Bcl2-inhibitable pathways that are activated in large part by Bim.[81,82] In B cells, CD40 signaling in concert with BCR and IL-4 signaling may rescue some cells from this self-destructive fate, and it is believed that these cells become long-lived memory cells.[83-86] There are also active mechanisms that signal cells to apoptose. One receptor–ligand pair called Fas and FasL is central in this process. Generally, when Fas is ligated by FasL, the cell expressing Fas is triggered to die by apoptosis.[87-90] Fas and FasL are not expressed at high levels on unstimulated resting lymphocytes. On activation, whereas T cells express both Fas and FasL, B cells express Fas.[90,91] Sensitivity to the Fas signal may be regulated in the Fas-expressing cell as well. Thus, after a certain degree of activation and proliferation, a T cell (expressing FasL) encountering an activated B cell (expressing Fas) may actually kill that B cell. There are likely other ligand pairs, particularly those in the tumor necrosis factor (TNF) family, that may serve similar functions, both for B and T cells.

A particularly interesting and instructive receptor ligand pair that downregulates ongoing responses has been elucidated. The receptor, CTLA4, is expressed on activated T cells, and when ligated, causes inactivation or death of the receptive T cell; it is said to therefore transduce a "negative" signal.[92-95] The other ligands in this pair are CD80 and to a lesser extent CD86, the same ligands that gives a positive signal to naïve T cells by ligating CD28. Thus, the same molecule can promote activation early on in the immune response while, through a change in the receptive T cell, it can inhibit activation at a later time. An analogous receptor pair of the B7 family are PD-1, an inhibitory receptor similar to CTLA-4, and its ligands PD-L1 and PD-L2. PD-1 is expressed on a number of activated lymphocytes and its ligands are constitutively and inducibly expressed on a variety of parenchymal cells (PD-L1) and dendritic cells (PD-L2).[96] Absence of these molecules leads to exaggerated immune responses and autoimmunity.[97-99] Most recently, data are emerging that PD-L1 and CD80 also interact strongly, with negative regulatory consequences that could be important for organ transplant rejection and autoimmunity in vivo.[100] These examples underscore the careful means by which the immune system regulates and dampens activation presumably to prevent autoimmunity.

Suppressor, or more commonly termed, *regulatory* T cells play critical roles in restraining many aspects of immune and autoimmune responses. The best-studied regulatory cell expresses CD25, the receptor for IL-2,[101,102] and its development and function is dependent on the expression of a key transcription factor, FoxP3.[103-105] These cells can prevent autoimmune syndromes such as inflammatory bowel disease, diabetes, and autoimmune encephalomyelitis in murine

models and can even be used to treat active disease.[106,107] They are also active in preventing transplantation rejection and GVHD. These cells may function by secreting suppressive cytokines, such as IL-10 and TGF-β, and also by cell–cell contact. Their critical role of regulatory T cells in humans is underscored by a rare and fatal inherited autoimmune disorder, IPEX (immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance), that results from a lack of FoxP3, which is needed for the development of CD25+ regulatory cells.[108,109]

How does regulation of ongoing immune responses prevent autoimmunity? In the first place, these normal forms of downregulation undoubtedly prevent common transient autoimmune responses from becoming chronic. More subtly, elimination or control of cells after immune responses will prevent the accumulation of a large number of self-specific memory cells. As long as such cells are rare, it is unlikely for autoreactive T cells and B cells, each specific for the same self-antigen, to wind up in the same place at the same time. Thus, downregulation and elimination of responding cells prevents a critical mass of self-reactive cells from ever forming.

Control of Self-Reactive Lymphocytes: Channeling the Type of Effector Response

A final layer of protection against self-inflicted immune damage involves channeling of responses so they are not harmful. Depending on the context, only certain effector functions will effectively eliminate certain pathogens. For example, antibodies will not be effective against intracellular pathogens. By analogy, only certain effector functions may cause autoimmune disease, depending on the circumstances. It is clear that there are two major types of T-helper cell responses, Th1 and Th2, that in turn lead to very different effector functions.[110-112] The propensity to make these various types of responses depends on a number of ill-understood factors, but these include genetics, route of antigen exposure, and dose of antigen.[113,114] Intriguingly, in certain murine models of autoimmunity such as the nonobese diabetic (NOD) model, experimental manipulations that shift responses away from Th1 and toward Th2 are highly protective against disease.[115-117] This is also relevant to B-cell autoimmunity per se because, through the use of different isotypes of Ig, different effector functions can occur. The cytokines secreted by Th1 and Th2 cells have profound effects on the isotypes of immunoglobulins that are produced during a response. Thus, not only is the T-cell component of the response channeled in this way, but the humoral response is also influenced. Recently, a new subset of T cells that secrete IL-17, thus dubbed Th17, has been recognized as important pathogenic cells in several autoimmune diseases, including experimental autoimmune encephalitis (and possibly the related spontaneous human disease, multiple sclerosis) as well as collagen-induced arthritis.[118] Th17 cells seem especially pathogenic in inflammatory bowel diseases.[119] At least some of these Th17 cells secrete a related cytokine, IL-22, which in turn may be responsible for their pathogenesis in diseases such as psoriasis.[120] Th17 cells depend on IL-6 and TGF-β for their development and IL-23 for their maintenance.[118] The transcription factor ROR-γt is required for these cells to differentiate, which they do to the exclusion of Th1 cells.[121] Th17 cells, although capable of promoting pathology in these autoimmune diseases, also must have essential functions for pathogen resistance. Indeed, emerging evidence indicates that Th17 cells are important for responses to extracellular bacteria as well.[118,122]

BREAKDOWN OF SELF-TOLERANCE IN AUTOIMMUNE DISEASES

Presumably, for autoimmune diseases and autoantibody production to occur, one or more of the multilayered mechanisms to prevent autoimmunity must fail. Surprisingly, the precise nature of these failures is not well understood. The mechanism of failure are likely different for the various autoimmune diseases and perhaps even for different patients with similar syndromes. Moreover, it seems likely both from phenomenologic and genetic studies that failures at several levels are required to generate clinically significant autoimmunity. In the following section, some examples of the current state of knowledge are given.

This chapter is not meant to review the nature of autoimmune diseases; however, before considering the likely points at which self-tolerance mechanisms break down, it is useful to review some basic concepts about these diseases. Grossly, autoimmune diseases have often been divided into organ-specific and systemic autoimmune syndromes. This classification is useful, but as these diseases are becoming better understood, the dividing lines are blurring; pathogeneses of all these diseases are likely to have much in common. In particular, systemic autoimmune diseases are actually much more specific in their antigenic targets than is commonly realized. Table 23-1 shows the types of autoantibodies commonly found in several systemic autoimmune diseases. Certain autoantibodies are diagnostic for specific autoimmune diseases, such as anti-Sm in SLE. Thus, Sm is a specific target in SLE, but patients with autoimmune diseases, such as rheumatoid arthritis, do not respond to this autoantigen. In fact, only 30% of all patients with SLE make anti-Sm, meaning that the other 70% are tolerant of their own Sm despite having a systemic

autoimmune disease.[123] Another salient feature of most human autoimmune diseases is adult onset. Both the selective nature of disease and its late onset argue against gross defects in the basic central tolerance mechanisms as being the cause.

Instead, these considerations suggest that most clinical autoimmune diseases are likely to arise from defects in the later stages of self-tolerance, such as preventing the activation of autoreactive cells or downregulating them when they are activated. Because in no case is the primary cause of a polygenic autoimmune disease known, it cannot be excluded that subtle defects in the earlier stages, including central tolerance, may also play a role; in fact, for some diseases, recent data suggest that there is a role for more "leaky" central self-tolerance.[124,125] However, it does seem clear that a gross defect in central tolerance would lead to a severe syndrome of congenital autoimmunity.

Genetic and Environmental Factors

Genetic Factors

Both genetic and environmental factors help to explain why autoimmunity occurs in some individuals and not others.[126] The most well-known genetic factor is the major histocompatibility complex, known as human leukocyte antigen (HLA) in humans. Many different autoimmune diseases are more or less associated with specific genotypes at this polymorphic locus. Among these are ankylosing spondylitis (HLA-B27), insulin-dependent diabetes mellitus (HLA-DR3/4), rheumatoid arthritis (HLA-DR4), and to some degree SLE (HLA-DR2/3).[127] It should be emphasized that although individuals with these genotypes are relatively more prone, most will not develop the autoimmune disease. How certain HLA genes predispose to autoimmunity is not very clear. These genes could be involved in the efficiency or specificity of central tolerance in the thymus but could also be involved in the activation of autoreactive T cells in the periphery. They could even control the efficiency with which the regulatory compartment of T cells develops.

Inheritance patterns of all systemic autoimmune diseases suggest that multiple genes, in addition to the HLA locus, contribute to susceptibility. Such genes are beginning to be identified in human and in animal models. This work has used "gene chips" that detect common variant single-nucleotide polymorphisms to identify and map genes that are associated with autoimmune phenotypes across large numbers of patients and control participants. This is currently being supplemented with whole-exon and in some cases whole-genome sequencing, which promises to find more rare genetic variants that are also likely to contribute to disease risk. Interestingly, risk alleles have been identified for a number of the same genes in more than one autoimmune disease; these include CTLA-4, STAT-4, PTPN-22, TNFAIP3, and IRF-5, all of which are known to regulate inflammation.[128-130] Analogous work—this time using crosses between susceptible and resistant strains—has allowed a number of predisposing genetic loci to be identified in murine autoimmune disease and their phenotypes investigated in greater detail.[131-135] Interestingly, most of them seem to have direct effects on B-cell function or activity. Table 23-2 lists categories of genes that are likely involved in genetic predisposition to autoimmune disease, drawing from both human and murine studies. Note that these include genes involved in the processes of antigen sequestration, T–B collaboration, and immune response downregulation that were discussed earlier as key features of the self-tolerance mechanisms that normally prevent autoimmune disease. In ongoing work, of the precise nature of defects in these genes may be defined; these include noncoding polymorphisms that affect expression levels in addition to structural alleles. This will in turn permit screening for defects in human autoimmune disease patients with the ultimate goals of aiding diagnosis, providing insights into pathogenic mechanisms, and guiding patient-specific therapies.

Although human genetic studies and animal models suggest multigenic inheritance, there are certain instructive cases in which single-gene defects play a major role. A well-studied example of mutations in these genes is the lpr/lpr mouse, a natural variant originally discovered at the Jackson Laboratories, which carries an inactivated murine Fas.[87,147,148] The gld mutation (another natural variant discovered at Jackson), which inactivates murine Fas ligand (FasL),[90] has a very similar phenotype to the lpr. Both of these mutations lead to an age-dependent autoimmune syndrome with autoantibody profiles that remarkably resemble human SLE.[148] These mice die prematurely of renal failure. They also have an accumulation of lymphocytes that leads to marked lymphadenopathy.[149] Presumably, this is the result of failure to eliminate postactivation T and B cells by the Fas-based mechanism.[150-152] Exactly how defects in the apoptotic Fas pathway lead to autoimmunity has yet to be elucidated. Interestingly, a rare syndrome in humans with incomplete penetrance, called *autoimmune lymphoproliferation syndrome,* has been traced to mutations in human Fas.[153] Often these patients are misdiagnosed with leukemia or lymphoma, and some have even been treated for (and survived) these neoplasms. Clonality and chromosomal studies in autoimmune lymphoproliferation syndrome reveal polyclonal B- and T-cell proliferations with normal karyotypes, in distinction with true lymphoma or leukemia. The phenotypes of these mutants in the Fas pathway, although more fulminant than most human autoimmune syndromes, illustrate two important points. They demonstrate the critical nature of the late downregulatory controls in preventing autoimmune disease. They also point out pathways in which less severe mutations might be discovered that account for human disease.

A final category of genes regulate the clearance of self-antigens and dead cells, which is particularly important in systemic autoimmune diseases such as SLE. These include complement components C4, C3, and C2, C1q, and less-known genes such as *MER,* which plays a role in signaling for the uptake of apoptotic fragments by macrophages.[145,146] Evidently, when self-antigens are not cleared promptly after cell death, they can become targets of the immune system, leading to autoimmunity to intracellular components such as chromatin.

As noted, TLRs can recognize some of these molecules when they are present in high concentrations, thus providing proinflammatory signals. In murine models of lupus, it has been demonstrated in vivo that TLR9 is required to generate antichromatin autoantibodies[154] and

Table 23-2 Genes Involved in Regulation of Autoimmune Responses

Category	Types of Genes*	Known Examples†
Central and peripheral deletion and anergy	Receptor signaling, MHC genes, receptor V genes	CD45,[126] PTPN22,[127-129] HLA (certain types2),[102] CD3,[131] CD4, CD8, CD28/B7[35]
Initiation of response	Receptor signaling, co-stimulatory molecules, adhesion molecules	BLK, STAT-4, IRF5, ITGAM, PTPN22, FcγRII[128,130]
Downregulation of response	Apoptosis genes, interleukins, negative costimulatory molecules	Fas,[110,112] TNF,[132,133] CTLA4,[89] CD40, CD3,[134] TNFAIP3,[130] CD28/B7[52,135]
Channeling of response	Interleukins, interleukin receptors	STAT-4,[130] IL-4, IL-10, IL-12, IFN-γ[88,99]
Autoantigen metabolism and apoptosis	Complement components, apoptosis signaling	C1q, C2, C4, DNAse I, MER[145,146]

that TLR7, which recognizes RNA, is required for the generation of autoantibodies to RNA-related antigens.[155] Indeed, a mutant mouse with a double dose of TLR7 develops spontaneous lupus with high levels of RNA antibodies.[156,157] Stimulation of these TLRs on specialized plasmacytoid dendritic cells leads to release of abundant type I interferon, which itself may be causally linked to lupus in mice and humans.[158] These findings highlight a genetic basis for recognizing self-molecules in autoimmune diseases and suggest new therapeutic targets that are currently being explored. Whether this theme extends to other autoimmune diseases beyond lupus remains to be determined.

Environmental Factors

Environment plays a role that is at least as important as genetics. This is illustrated by the fact that concordance rates among identical twins, even raised in the same household, are surprisingly low. Only 20% of twins of patients with rheumatoid arthritis also get rheumatoid arthritis.[127] There are many examples of environmental factors causing either chronic or transient autoimmune diseases. There are postinfectious syndromes such as postmycoplasmal cold agglutinin disease. The pattern of incidence of multiple sclerosis suggests a viral etiology, although no causative virus has ever been convincingly demonstrated. Another category of infectious associations includes postviral myocarditis, which follows certain coxsackievirus infections.[76] It is sometimes conceptually difficult to draw a line between viral damage and consequent immune system damage; however, if sensitization to self-antigens occurs as a consequence of viral infection and these later are pathogenic targets independent of viral antigens, it seems reasonable to consider the syndrome as autoimmune.

Infections are not the only source of environmental stimuli for autoimmunity. Toxins, such as mercury, cause autoimmunity in animal models.[159,160] Another form more familiar to those in hematology is drug-induced autoimmunity, as in AIHA. Drugs, such as procainamide, that cause lupus-like syndromes are particularly prominent examples.[161,162] Despite these specific examples, the environmental factors that play a role in promoting common autoimmune diseases such as rheumatoid arthritis or SLE are unknown.

Examples in Hematology: Epitope Spreading in Posttransfusion Purpura

One potential way to break self-tolerance may be particularly relevant to syndromes found in hematology and is worthy of elaboration. This is a form of environmental stimulation, albeit iatrogenic. In PTP, transfusion with allogeneic platelets that contain a platelet-specific antigen (e.g., HPA-1a) lacking in the recipient (which in this case would be HPA-1b) leads to rapid destruction of the transfused platelets and antibody formation to the foreign platelet antigen.[3,163] However, several days later, the recipient becomes severely thrombocytopenic owing to increased destruction of the recipient's own platelets. Although how such destruction of self-platelets occurs secondary to destruction of allogeneic platelets may still be controversial,[3,163,164] the best explanation is an autoimmune response.[1-3] How does this response get stimulated? The probable pathway bears significant parallels to one demonstrated in mice a number of years ago by Janeway and colleagues.[165,166] These workers immunized normal mice with human cytochrome c, which differed slightly from endogenous murine cytochrome c. The mice made both an antibody response and a T-cell response to the human cytochrome c; however, because the human and mouse cytochromes are so similar, the antibody response (but not the T-cell response) cross-reacted with murine cytochrome c. Presumably, this reflected activation of ignorant B cells with specificity for self-cytochrome c (and also human). However, several weeks later, if the mice were given a dose of self-cytochrome c, now both a vigorous B-cell and T-cell antiself response ensued. These authors suggested that priming with the cross-reactive antigen first induced self-reactive B cells, which in turn could then break tolerance in anergic or ignorant self-reactive T cells.

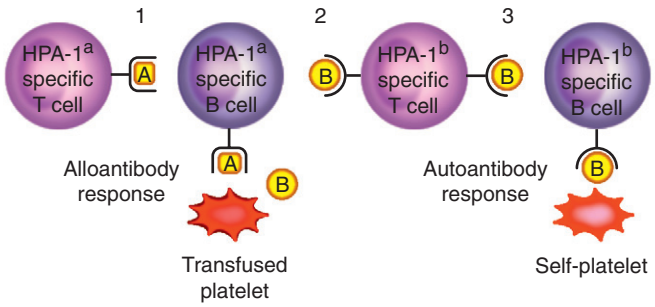

Figure 23-6 EPITOPE SPREADING AS A POSSIBLE AUTOIMMUNE MECHANISM FOR POSTTRANSFUSION PURPURA (PTP). Events are depicted as progressing from left to right. An HPA-1^{b} person is transfused with an HPA-$1^{a/b}$ platelet product. An alloantibody response ensues as an HPA-1^{a}-specific B cell recognizes the platelet, becomes activated to secrete antibody, and presents the HPA-1^{a} antigen to an anti-HPA-1^{a} T cell *(step 1)*. In addition, the activated B cell may now activate a previously ignorant anti-HPA-1^{b}-specific T cell to initiate an autoimmune response *(step 2)*. The activated B cell acquired the self-HPA-1^{b} antigen as a passenger on the HPA-$1^{a/b}$ allogeneic platelet. This autoreactive T cell can then activate an ignorant anti-HPA-1^{b} B cell to make an autoantibody response *(step 3)* in response to autologous platelets. Note that the sensitization involved in *steps 1 and 2* may take place in a primary response during the first transfusion or exposure and that *step 3* may take place in a clinically noticeable way only after a secondary exposure to homologous platelets.

How does this relate to PTP? Fig. 23-6 illustrates the author's hypothetic adaptation of this mechanism to the platelet transfusion situation. The foreign platelets actually share many common antigens with the host, as well as differ at the HPA-1a locus. The foreign antigenic difference allows ignorant self-specific B cells (as well as HPA-1a-specific B cells) to interact with helper T cells that are specific for the foreign HPA-1a antigen and become activated. Moreover, these activated B cells can then present self-platelet antigens along with costimulatory signals to self-reactive T cells. When this happens, the immune response can perpetuate even in the absence of the foreign platelets. This is exactly what is seen in PTP, in which a delayed response continues to eliminate self-platelets for many days after the disappearance of the transfused platelets. Thus, a foreign platelet is analogous to foreign cytochrome c in having a few different antigens along with many shared antigens. In the same way as shown experimentally with cytochrome c, it is hypothesized that the few foreign antigens existing on the same particle (in the case of cytochrome c, it is the same molecule) allow spreading of autoimmunity from a foreign antigen to self-antigens. The key events are the activation of ignorant B cells that cross-react with both self and foreign molecules and then the activation by these B cells or T cells that are specific for self.

It is reasonable to question how such antiself responses are ever stopped once started. PTP, for example, is a self-limited syndrome. In fact, the answer is not known; however, both downregulation of antigen as the platelet count falls to near zero, and the natural mechanisms that cause apoptosis of responding lymphocytes probably play a role. Regulatory T cells could also help bring the response under control. In the absence of an autoimmune-prone host who has mutations affecting the downregulation of immune responses, these autoimmune reactions will remain transient. It is speculated that when similar events—for example, a response to a viral DNA-binding protein that eventually spreads to allow for responses to self-DNA and chromatin, as in SLE—occur in people who do have genetically based problems in downregulating such responses, a chronic autoimmune syndrome can be induced.

IMPLICATIONS AND THERAPY

The significance of this issue to hematology ranges from syndromes such as AIHA and idiopathic thrombocytopenic purpura to

iatrogenically induced autoimmunity as in PTP. In the latter case, a phenomenon known as *epitope spreading,* which is documented in murine models, but little discussed in terms of PTP, is speculated to be a relevant pathogenetic mechanism. A basic understanding of the mechanisms of self-tolerance and their breakdown in autoimmune disease raises the possibility of many types of specific therapeutic interventions. One of the clearest would be to identify initiating factors, such as infections, and to prevent or treat them. A second approach would be to reset tolerance. Some of the previous examples, such as in PTP, illustrate how an initiating event can be amplified, leading to broken tolerance. If the system can be set back to the state before that event, the disease could be cured. At present, it is unclear how to do this; however, an autologous or even allogeneic hematopoietic stem cell transplant may have the desired effect. In fact, this sort of radical therapy has been tried in selected cases of severe SLE and seems to have some efficacy.[167] Another promising area is in channeling the immune response, particularly as the steering mechanisms are becoming better understood at the molecular level. Work in this area is currently active. A third area is to design more specific modulators of inflammation, including interfering with costimulatory signals. These latter approaches have seemed promising in various animal models, although issues with unexpected effects on clotting have arisen in clinical trials of CD40L inhibition.

Current therapy is much more crude and typically involves general nonspecific immunosuppression either with steroids or cytotoxic drugs. Although these therapies can be effective, they have numerous undesirable side effects, not the least of which is increased susceptibility to infection caused by immunosuppression. More promising are drugs that inhibit the effects of TNF-α, which have proven successful in modifying progression of rheumatoid arthritis and also in inflammatory bowel disease, psoriasis, and GVHD.[168-170] Recently, additional proinflammatory cytokines, such as IL-6 and IL-12/23, have been targeted by monoclonal Ab as effective therapies in patients.[171,172] This approach, although a result of modern biotechnology and our understanding of immunopathogenesis, still targets effector function of the immune system and does not modify the root cause of disease. Therapies should ultimately be directed toward either prevention or else specific downregulation of ongoing responses. Recently, rituximab, an antibody to CD20 that depletes B cells and is effective in treating non-Hodgkin lymphoma, has been used to treat a variety of autoimmune syndromes. It is showing great promise[173,174] and it has been approved to treat some rheumatoid arthritis patients.[175] In a similar vein, BLyS (B-lymphocyte stimulator), which is a survival factor for B cells, has been successfully targeted via a monoclonal Ab that leads to B-cell depletion.[176,177] This compound, belimumab, was recently granted U.S. Food and Drug Administration approval for the treatment of SLE. It will be interesting to determine whether B-cell depletion leads to long-term remissions, perhaps by interrupting positive feedback loops such as illustrated in Fig. 23-6. Future work will include continuing to define how self-tolerance is imposed and how it is broken in disease, what the critical triggers and autoantigens are, and how to use immunomodulation to treat autoimmune diseases on the basis of a better understanding of the pathogenesis.

CHAPTER 24

BIOLOGY OF ERYTHROPOIESIS, ERYTHROID DIFFERENTIATION, AND MATURATION

Thalia Papayannopoulou and Anna Rita Migliaccio

The production of erythroid cells is a dynamic and exquisitely regulated process. The mature red cell is the final phase of a complex but orderly series of genetic events that initiates when a multipotent stem cell commits to the erythroid program. Expression of the erythroid program occurs several divisions later in a greatly amplified population of erythroid cells, which have a characteristic form and structure, maturation sequence, and function. These maturing cells are termed *erythroid precursor cells* and *reticulocytes*. Terminally differentiated cells have a finite life span, and they are constantly replenished by influx from earlier compartments of progenitor cells that are irreversibly committed to express the erythroid phenotype. During ontogeny, successive waves of erythropoiesis occur in distinct anatomic sites. Erythroid cells developing in these sites have distinguishable phenotypes and intrinsic programs that are dependent on gestational time and their microenvironment. At each site, erythroid cells are in intimate contact with other cells (e.g., stromal cells, hematopoietic accessory cells, and extracellular matrix) composing their microenvironment. Within this microenvironment, erythroid development is influenced by cytokines, which are either elaborated by microenvironmental cells or produced elsewhere and then entrapped in the extracellular matrix.

Knowledge of the properties of erythroid progenitor and precursor cells and their complex interactions with the microenvironment is essential for understanding the pathophysiology of erythropoiesis. Aberrations in the generation and/or amplification of fully mature and functional erythroid cells or in the regulatory influences of microenvironmental cells or their cytokines/chemokines form the basis for various clinical disorders, including aplasias, dysplasias, and neoplasias of the erythroid tissue.

ERYTHROID PROGENITOR CELL COMPARTMENT

The erythroid progenitor cell compartment, situated functionally between the multipotent stem cell and the morphologically distinguishable erythroid precursor cells, contains a spectrum of cells with a parent-to-progeny relationship, all committed to erythroid differentiation. A complete understanding of how erythroid commitment is achieved at the biochemical or molecular level is lacking, although some attempts at determining the molecular basis have been made.[1-4] Evidence from in vitro cultures of single multipotent progenitor cells allowed to differentiate in competent environments, as well as evidence obtained by studying the phenotype of leukemic cells, suggests that commitment to a specific hematopoietic lineage is accomplished not by acquisition of new genetic information but by restriction (probably on a stochastic basis) to specific programs from a wider repertoire available to pluripotent progenitor cells.[5,6] Molecular evidence supports this view.[6-8] Although all erythroid progenitor cells share the irreversible commitment to express the erythroid phenotype, the properties of these cells progressively diverge as the cells become separated by several divisions.

Erythroid progenitor cells are sparse (Table 24-1) and difficult to isolate in sufficient purity and numbers for study. For these reasons, the existence and characteristics of these cells were inferred from their ability to generate hemoglobinized progeny in vitro in clonal erythroid cultures (Fig. 24-1). Two classes of progenitors have been identified using this approach.[9] The first, more primitive class consists of the burst-forming unit–erythroid (BFU-E), named for the ability of BFU-E to give rise to multiclustered colonies (erythroid bursts) of hemoglobin-containing cells. BFU-E represent the earliest progenitors committed exclusively to erythroid differentiation and a quiescent reserve, with only 10% to 20% in cycle at any given time. However, once stimulated to proliferate in the presence of appropriate cytokines, BFU-Es demonstrate a significant proliferative capacity in vitro, giving rise to colonies of 30,000 to 40,000 cells, which become fully hemoglobinized after 2 to 4 weeks, with a peak incidence at 14 to 16 days. They have a limited self-renewal capacity; at least a subset of BFU-E is capable of generating secondary bursts upon replating. In contrast to this class of progenitor cells, a second, more differentiated class of progenitors consists of the colony-forming unit–erythroid (CFU-E). Most (60% to 80%) of these progenitors already are in cycle and thus proliferate immediately after initiation of culture, forming erythroid colonies within 7 days. Because CFU-E are more differentiated than BFU-E, they require fewer divisions to generate colonies of hemoglobinized cells, and the colonies are small (8 to 64 cells per colony).

Although the two classes of committed erythroid progenitors (BFU-E and CFU-E) appear distinct from each other, in reality progenitor cells constitute a continuum, with graded changes in their properties. Only progenitor cells at both ends of the differentiation spectrum have distinct properties. Perhaps the earliest cell with the potential to generate hemoglobinized progeny is an oligopotent progenitor, which is capable of giving rise to mature cells of at least one other lineage (granulocytic, macrophage, or megakaryocytic) in addition to the erythroid. This progenitor, a multilineage colony-forming unit (CFU) called a *colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte* (CFU-GEMM) or *common myeloid progenitor,* and the most primitive BFU-E have physical and functional properties that are shared by both pluripotent stem cells and progenitor cells committed to nonerythroid lineages. These properties include high proliferative potential, low cycling rate, response to a combination of cytokines, and presence of specific surface antigens or surface receptors (see Table 24-1). In contrast, the latest CFU-E have many similarities with erythroid precursor cells and little in common with primitive BFU-E. Their proliferative potential is limited, they cannot self-renew, they lack the cell surface antigens common to all early progenitors, and they are exquisitely sensitive to erythropoietin (EPO; see Table 24-1).

Although clonal erythroid cultures are indispensable for the study of erythroid progenitors, they do not faithfully reproduce the in vivo kinetics of red cell differentiation/maturation, and many maturing cells have a megaloblastic appearance and lyse before they reach the end stage of red cell development. In vivo, erythropoiesis probably occurs faster than predicted from culture data. For example, studies in dogs with cyclic hematopoiesis, a genetic stem cell defect leading to pulses of hematopoiesis, provide evidence that BFU-E mature to CFU-E over 2 to 3 days in vivo, although this process may require 5 to 6 days in canine marrow cultures.[10]

Erythroid progenitors can be cultured in serum-depleted media,[11,12] as well as in serum-containing media. The effects of recombinant growth factors can be studied in serum-depleted cultures without the complicating influences of multiple or unknown factors present in

Table 24-1 Changes in the General Properties During the Differentiation of Erythroid Progenitors

	CFU-GEMM (CMP)	BFU-E	CFU-E
GENERAL FEATURES

BFU-E, Burst-forming unit–erythroid; *CFU-E,* colony-forming unit–erythroid; *CFU-GEMM (CMP),* colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (common myeloid progenitor); *EKLF,* erythroid Krüppel-like factor; *EPO,* erythropoietin; *FL,* Flt-3 ligand; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *HCAM,* homing-associated cytoadhesion molecule; *HLA,* human leukocyte antigen; *IL,* interleukin; *KL,* KIT ligand; *SCL,* stem cell leukemia; *TGF,* transforming growth factor; *TPO,* thrombopoietin.
*23.6 (SFL 23.6) is a monoclonal antibody reactive with CFU-E, erythroblasts, and erythrocytes.[577]
†ABH and Ii are blood group antigens.
‡Presence of other cytoadhesion molecules (i.e., CD31, L-selectin, P-selectin, E-cadherin) has been described in progenitors (see text). However, the extent of their presence in BFU-E as compared to other cells is not clear.

serum. Conditions that imitate lower oxygen pressures, found in bone marrow in vivo, favorably influence erythroid development in culture and may be advantageous.[13]

BFU-E are generated from multipotent or oligopotent progenitors within the marrow, and their survival and proliferation are dependent on the presence of cytokines, elaborated by either stromal cells or accessory cells within the microenvironment. A number of cytokines influence proliferation and/or survival of early progenitors. Among the cytokines, KIT ligand (KL, also known as *stem cell factor,* SCF), which is produced by stromal cells, and interleukin (IL)-3, which is produced by a subset of T cells, alone and in synergy, have a profound proliferative effect on BFU-E and its progeny. Other cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-11, and thrombopoietin (TPO), stimulate a subset of BFU-E.[14-16] Cytokines exert their effects through interaction with specific receptors present on the BFU-E surface. The presence of such receptors also has been documented in the leukemic counterparts of normal BFU-E and in leukemic cell lines.[17] BFU-E in culture cannot survive for more than a few days in the absence of cytokines. If they are deprived of cytokines for more than 6 days, more than 80% of BFU-E are lost.[18] In addition to positive regulators (IL-3, GM-CSF, TPO, KL, and IL-11), substances with negative influences on BFU-E proliferation have been identified. They include tumor necrosis factor-α (TNF-α), tumor necrosis factor–related apoptosis-inducing ligand (TRAIL), transforming growth factor-β (TGFβ), and interferon-γ.[19-21] These negative regulators are responsible, at least in part, for the anemia associated with chronic inflammatory states. The effects of TNF-α and TRAIL are mediated through induction of apoptosis at specific stages of erythroid maturation. In the case of TRAIL, a complex system of signaling and decoy receptor isoforms determines the precise cell window susceptible to TRAIL-induced apoptosis.[21] TRAIL probably induces apoptosis by competing with EPO for activation of Bruton tyrosine kinase. Its effects are counteracted by KL[22,23] and protein kinase Cε[24] signaling. TRAIL also is involved in the pathobiology of the anemia associated with multiple myeloma (TRAIL is overproduced by the malignant plasma cells of these patients[25]) and myelodysplastic syndrome (MDS) (myelodysplastic erythroid progenitors overexpress the adaptor Fas-associated death domain of the TRAIL receptor[26]). On the other hand, the negative effects of TGFβ[27] are mainly achieved by accelerating cell

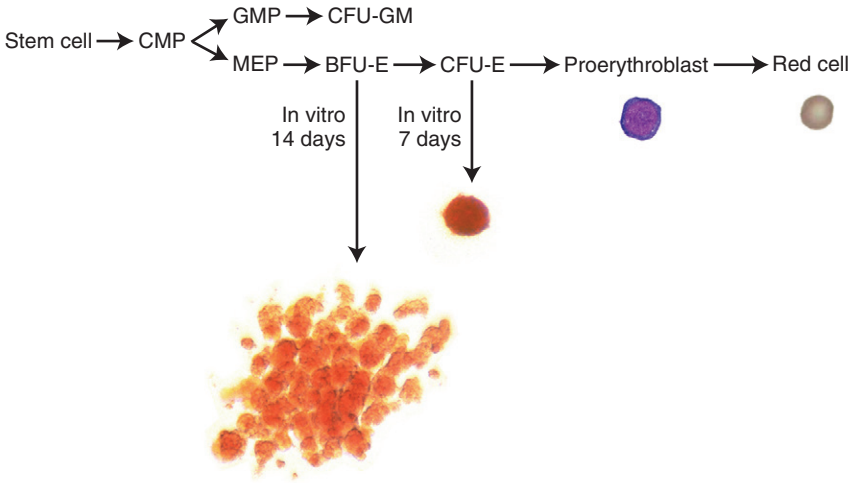

Figure 24-1 CELLULAR MODEL OF ERYTHROID DIFFERENTIATION. Multipotent stem cells generate cellular compartments defined on the basis of their antigenic profile and restricted toward the myeloid differentiation pathway–defined common myeloid progenitor (CMP).[68,69] CMP in turn give rise to granulocyte/macrophage progenitor (GMP) and megakaryocyte-erythroid progenitor (MEP), which probably correspond to the burst-forming unit–erythroid (BFU-E). Lastly, MEP generate cells capable of unilineage differentiation toward either the megakaryocytic (colony-forming unit-megakaryocyte [CFU-Mk], not shown) or the erythroid pathway (colony-forming unit–erythroid [CFU-E]). These cells occur infrequently in the marrow (approximately 0.3% of mononuclear cells) and are defined on the basis of clonogenic assays. If marrow is placed in semisolid medium (e.g., methylcellulose) to decrease cell motility, with appropriate nutrients and growth factors (e.g., transferrin, insulin, erythropoietin, and interleukin-3), CFU-E (after approximately 7 days) differentiate into small clusters of hemoglobinized or red cells termed *erythroid colonies*. Most BFU-E present in the inoculum differentiate to form multiclustered colonies of hemoglobinized cells, or erythroid bursts, by days 14 to 16. Each erythroid colony or burst derives from one BFU-E or CFU-E, respectively. *CFU-GM,* Colony-forming unit–granulocyte-macrophage.

differentiation, whereas data on mouse models of chronic exposure indicate that interferon-γ reduces the erythrocyte life span and inhibits erythropoiesis by promoting the expression of PU.1, a transcription factor that antagonizes GATA1, a master transcriptional regulator of erythropoiesis[28,29] (see Transcription Factors in Erythropoiesis).

In addition to the negative growth factors, overexpression of hepcidin, a key regulator of systemic iron homeostasis (see Chapter 33), is involved in determining the anemia associated with chronic inflammation.[30] The increased hepcidin synthesis that occurs during inflammation traps iron in macrophages, decreases plasma iron concentrations, and causes iron-restricted erythropoiesis characteristic of the anemia of inflammatory states. Hepcidin deficiency induces iron overload in transgenic mice, whereas hepcidin excess induces iron accumulation in macrophages similar to observations in patients with chronic inflammation.[31] Hepcidin might inhibit proliferation of erythroid progenitors at low EPO concentrations.[32]

BFU-E and immediate progeny (but not CFU-E) are motile cells found in significant numbers in peripheral blood. As with BFU-E, the ability of stem cells and progenitor cells to circulate is physiologically important for the redistribution of marrow cells in cases of local damage to the microenvironment and for reconstitution of hematopoiesis after transplantation. The spectrum of BFU-E in circulation probably is narrower (consisting mostly of early, quiescent BFU-E) than that of BFU-E in the bone marrow; otherwise, their properties are similar to those of marrow BFU-E. The number of circulating BFU-E (along with other progenitors and stem cells) can increase to significant levels after cytokine/chemokine treatments and after chemotherapy, a finding that has been exploited for transplantation purposes.[33] At present, mononuclear cells contained in the blood from subjects mobilized with granulocyte colony-stimulating factor (G-CSF) are routinely used as a source of stem/progenitor cells in autologous and allogeneic transplantation,[34] alone or in combination with AMD3100, a CXCR4 inhibitor.[35]

In addition to forming colonies in semisolid medium, hematopoietic progenitors from different sources can generate erythroid cells in liquid culture.[36] Liquid cultures do not allow progenitor cell enumeration but may generate more differentiated cells per progenitor cell than do semisolid cultures.[37,38] The number of erythroblasts generated in liquid cultures can be further increased by adding to the media glucocorticoid steroids,[37,39] which exert a reversible inhibition on proerythroblast maturation.[40,41] In theory this culture system may generate numbers of erythroid cells equivalent to 1 unit of blood from discarded stem cell sources (cord blood <50 mL and from buffy coats produced during the leukoreduction process of blood donations).[42,43] This recognition led to the belief that red blood cells generated ex vivo may one day be used for transfusion. Recently it has been demonstrated that red blood cells generated *in vitro* from mobilized $CD34^{pos}$ cells collected by apheresis have normal survival when transfused into an autologous recipient.[44] Although production of red blood cells in numbers required for transfusion is currently a challenging proposition (approximately 2.5×10^{12}), this first-in-man proof-of-principle has fostered great interest in studies addressing the various aspects of the complex process of making red blood cells in vitro to ultimately translate this approach into clinical transfusion practice.

Surface antigens of human BFU-E have been defined through the use of monoclonal antibodies.[45,46] The antibodies tested include two broad categories: antibodies raised against leukemic cells or cell lines with progenitor cell properties, and antibodies raised against normal, terminally differentiated red cells. Enrichment in BFU-E (or CFU-E) after labeling with these antibodies, or their loss after complement-dependent lysis, is considered indicative of the presence of test antigens on the BFU-E surface. Reactivities of BFU-E with several antibodies directed against defined surface antigens are listed in Table 24-1. Like other hematopoietic progenitors, BFU-E display human leukocyte antigen (HLA) class I (A, B, C) and class II (DP, DQ, DR) antigens on their surface. Class II antigens (especially the products

of the DR locus), in contrast to class I, are variably expressed among BFU-E. This may relate to variations in their cycling status, because myeloid progenitors in S phase have relatively higher expression of class II antigens.[47] The presence of HLA class II antigens (DR and, to a lesser extent, DP and DQ) most likely allows BFU-E to recognize and interact with the immunoregulatory cells (e.g., T cells, monocytes), which also express class II determinants.[48] In addition to HLA antigens, several other antigenic structures are found on cells within the BFU-E compartment (see Table 24-1). The best representative of these is the CD34 antigen, which has been successfully exploited for isolation of BFU-E and other progenitors. CD34 is a highly *O*-glycosylated cell surface glycoprotein. It is expressed in all hematopoietic progenitors and vascular endothelial cells.[49] The role of CD34 in human hematopoiesis is not clearly defined. The numbers of all hematopoietic progenitors were reduced in CD34 "null" murine embryos and adult animals, but no other abnormalities were identified.[50] Expression of CD34 was low or absent in a population of adult long-term repopulating cells in mouse[51] and in man.[52] However, the clinical significance of this finding is not clear because of the fluctuating expression of CD34[53] and the difference in regulatory mechanisms of CD34 gene expression in mouse and human stem cells.[54] Furthermore, use of antibodies or conjugated ligands determined that BFU-E present in enriched progenitor preparations display receptors for KL, EPO, TPO, GM-CSF, IL-3, IL-6, and IL-11. However, the majority of BFU-E, in contrast to myeloid progenitors (colony-forming unit–granulocyte-macrophage), do not express the restricted hematopoietic phosphatase CD45RA.[55,56] Furthermore, BFU-E appear to share with late colony-forming unit-megakaryocyte progenitors the expression of the TPO receptor (c-Mpl or TPO-R)[56,57] and glycoprotein IIb/IIIa (CD41), a marker of the divergence between definitive hematopoiesis and endothelial cells during development.[58]

As BFU-E mature to the CFU-E stage, they begin to express surface proteins characteristic of erythroblasts, the morphologically recognizable erythroid cells. For example, CFU-E express Rh antigens and the erythroid-specific sialoglycoprotein glycophorin A. Blood group antigens of the ABH Ii type are detectable in a subset of CFU-E. In contrast, CD34 molecules, class II antigens, and certain growth factor receptors (i.e., IL-3R, C-KIT) are greatly diminished or virtually absent at the CFU-E stage (see Table 24-1). The most important functional difference between BFU-E and CFU-E is the abundance of erythropoietin receptors (EPORs) on CFU-E and their dependence on EPO for cell survival. CFU-E, in contrast to BFU-E, cannot survive in vitro even for a few hours in the absence of EPO. Although greater than 80% of CFU-E have detectable EPORs,[59] only a small proportion of BFU-E have receptors[60,61] and can terminally differentiate in culture in the presence of EPO alone.[62] Direct binding studies show that the number of EPORs peaks at the CFU-E/proerythroblast level and progressively declines when cells mature further (see Table 24-1),[59] reflecting the declining influence of EPO. In addition to the abundance of EPORs, erythroid progenitors are distinguished from other marrow progenitors by the presence of high levels of transferrin receptors (TfRs).[60,63,64] Peak levels of TfRs are seen on CFU-E and erythroid precursors, and lower levels are present on reticulocytes.[57,63] (For a detailed review of iron metabolism and heme synthesis in erythroid cells, see references 65 to 67).

In addition to the functional definition, the hemopoietic compartments in the marrow of a normal adult mouse have been prospectively identified on the basis of expression of specific cell surface antigens and subsequent differentiation in vitro and in vivo.[68] The $Lin^{neg}IL\text{-}7R^{neg}Thy1^{neg}C\text{-}KIT^{pos}Sca1^{neg}$ fraction of the marrow of normal adult mice has been subdivided into three populations based on the expression of CD34 and CD16/CD32: $CD16/CD32^{low}CD34^{high}$ representing the common myeloid progenitor (CMP), $CD16/CD32^{low}CD34^{low}$ representing the megakaryocyte/erythroid progenitor (MEP), and $CD16/CD32^{high}CD34^{high}$ representing the granulocyte/macrophage progenitor (see Fig. 24-1).[68] Many laboratories have also prospectively identified the corresponding human compartments.[69-71] In humans, the transition from CMP to MEP is characterized by loss of aldehyde dehydrogenase activity[72] and acquisition of c-Mpl expression.[73]

The correlation between phenotype and function of cells isolated on the basis of these antigenic expression profiles is not maintained under conditions of perturbed or stressed erythropoiesis. Stress activates the bone morphologic protein 4 (BMP4)/hedgehog signaling, which induces the generation of erythroid progenitor cells with a unique phenotype, KIT^{pos}, $CD71^{pos}$ and $TER\text{-}119^{pos}$ (TER-119 recognizes the murine equivalent of glycophorin A).[74,75] The expression on these cells of "true" markers of terminal erythroid maturation suggests that stress-specific erythroid progenitors may be related to the proerythroblasts with extensive proliferative potential generated in mice after EPO treatment or anemia challenge,[76,77] thereby indicating that stress may uncouple proliferation and differentiation programs during terminal erythroid maturation. The proliferation and differentiation programs are also uncoupled during ontogenesis. The number of erythroblasts generated in vitro by embryonic/primitive (E7.5 yolk sac), embryonic/definitive (E8.5-9.5 yolk sac and E12.5 fetal liver), and adult/definitive murine erythroid progenitors in the presence of EPO, KL, and dexamethasone differ widely.[78] Embryonic/definitive proerythroblasts originating from a transient wave of early fetal erythropoiesis are capable of generating large numbers (10^{10}- to 10^{30}-fold expansion) of proerythroblasts that, because of their great expansion potential, were characterized as extensively self-renewing erythroblasts (ESREs). By contrast, under the same conditions, embryonic/primitive proerythroblasts failed to expand and adult/definitive proerythroblasts expanded only 10^{2}- to 10^{5}-fold. Interestingly, human erythroblasts generated in the presence of dexamethasone also express high levels of C-KIT and acquire self-renewal potential.[79] In addition to steroids, polymeric immunoglobulin A1 (IgA1) has also been shown to control erythroblast proliferation and to accelerate erythropoiesis recovery in anemia.[80] These observations challenge the notion that erythroblasts are capable of a limited (at most two to four) number of divisions.

More recently, erythroid cells have been derived in vitro from stem cell sources with unlimited proliferation potential such as human embryonic stem cells (hESCs) and induced pluripotent stem cells (iPSCs).[81] Seminal studies in 2008 from Hiroyama et al established that red blood cells generated from murine ESCs are functional in vivo because they protect mice from lethal hemolytic anemia.[82] Methods for generating red blood cells from human ESCs have also been published, and the biologic properties of these human ESC-derived red blood cells have been extensively characterized.[83,84] A number of groups have also published methods for generating red blood cells from iPSCs.[85,86] In general, independently of their origin, ES- or iPS-derived erythroid cells express mostly embryonic and fetal globins. In addition, several investigators are exploring the feasibility of reprogramming somatic cells directly into erythroid cells, bypassing the pluripotent state and/or generating stem cells with unlimited expansion potential by epigenetic or genetic in vitro treatments.[87,88] In both cases, the modified cells generated erythroblasts that mature into circulating red cells when injected into immunodeficient NOD/SCID/γc^{null} mice.

ERYTHROID MORPHOLOGICALLY RECOGNIZABLE PRECURSOR CELL COMPARTMENT

The erythroid precursor cell compartment, also termed the *erythron,* includes cells that, in contrast to the erythroid progenitor cells (BFU-E and CFU-E), are defined by morphologic criteria. The earliest recognizable erythroid cell is the *proerythroblast,* which after four to five mitotic divisions and serial morphologic changes gives rise to mature erythroid cells. Its progeny include basophilic erythroblasts, which are the earliest daughter cells, followed by polychromatophilic and orthochromatic erythroblasts. Their morphologic characteristics reflect the accumulation of erythroid-specific proteins (i.e., hemoglobin) and the decline in nuclear activity (Fig. 24-2). After the last mitotic division, the inactive dense nucleus of the orthochromatic erythroblast moves to one side of the cell and is extruded, encased by a thin cytoplasmic layer with differential partitioning of membrane/cytoplasmic proteins.[89] Expelled nuclei are ingested by marrow

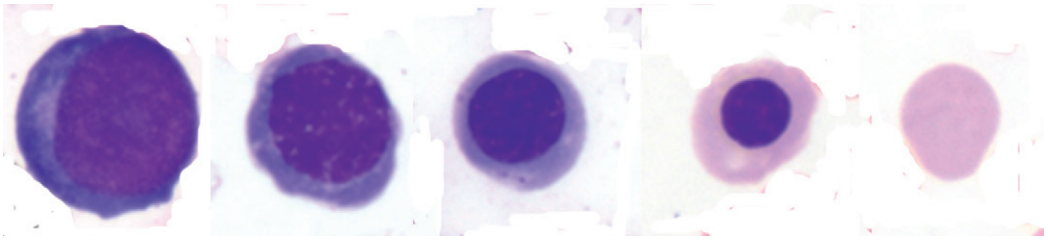

Figure 24-2 ERYTHROID MATURATION SEQUENCE. As proliferation parameters (i.e., rates of deoxyribonucleic acid [DNA] and ribonucleic acid [RNA] synthesis) and cell size decrease, accumulation of erythroid-specific proteins (i.e., heme and globin) increases, and the cells adapt their morphologic characteristics. *(Modified from Granick S, Levere R: Heme synthesis in erythroid cells. In Moore CV, Brown EB, editors:* Progress in hematology, *vol 4, Orlando, Fla, 1964, Grune & Stratton, p 1.)*

macrophages, and the resulting enucleated cell is a reticulocyte. Although all mammals have enucleated cells in their circulation, the evolutionary advantage of enucleation is not readily apparent. It may allow for more red cell deformability when traveling through the small vasculature, or it may minimize cardiac workload.

Maturation from proerythroblast to reticulocyte likely does not always adhere to a rigid sequence in which each division is associated with the production of two more differentiated and morphologically distinct daughter cells (i.e., basophilic erythroblast gives rise to two polychromatophilic ones). Rather, significant flexibility, both in the number and rate of divisions and in the rate of enucleation, may be allowed. Such deviations from the normal orderly maturation sequence may be dictated by the level of EPO or "stress" conditions. Thus in cases of acute demand for red cell production (because of blood loss or hemolysis), the kinetics of formation of new reticulocytes are significantly more rapid. Resulting red cells may be larger (i.e., with increased mean corpuscular volume). This has led to the concept of "skipped" divisions.[90] The orderly unilineage differentiation pathway shown in Fig. 24-1 likely is restricted to conditions of steady-state hematopoiesis. Similar to occurrences in the lymphoid system,[91] alternative routes are taken under conditions of "stress." Murine models have been developed to address phenotype-function cell relationships during recovery from acute and chronic erythroid stress. A model for acute stress is represented by the hemolytic anemia induced by phenylhydrazine treatment. Recovery from this acute anemia involves recruitment of the spleen as an additional erythropoietic site and is dependent on EPO. The amount of ^{3}H-thymidine incorporated by splenic erythroblasts produced in response to this stress initially represented the biologic assay for EPO.[92] Genetic evidence indicates that recovery from this hemolytic anemia is controlled by a receptor complex formed between the EPOR and a truncated version of the Stk receptor encoded by Fv2^{s}, a locus that also determines strain susceptibility to Friend virus infection.[93] An additional control on the response to acute erythroid stress in mice is exerted by the glucocorticoid receptor (GR), because mice in which this receptor is targeted recover poorly from phenylhydrazine treatment.[94] On the other hand, experimentally induced mutations in genes involved in the regulation of erythroid differentiation, such as signal transducer and activator of transcription 5 (STAT5^{null} [95]) and GATA1^{LOW}[96], or inability of response to reactive oxygen species (ROS) challenge (i.e., Foxo3 deficiency)[97] increase the rate of erythroblast apoptosis. The spleen is also recruited as a hemopoietic site in response to chronic erythroid stress.[95,96] Several studies in aggregate suggest that the erythron does not respond to stress only by amplifying the normal erythroid progenitor cell compartments (i.e., CMP, MEP, and CFU-E), but by generating alternative routes of differentiation, possibly through cooperation between EPOR and other receptors (e.g., Stk, GR, soluble KL, BMP4/hedgehog pathway) specifically recruited as part of the stress response.[76,77,98,99] Genetic heterogeneity in the control of gene expression of these receptors may add another layer of variability in recovery from anemia in humans.

The importance of GR in the control of stress erythropoiesis was established by studies in transgenic mice harboring a dimerization-defective GR (GR$^{dim/dim}$ mice).[100] These mice have normal steady-state erythropoiesis but were unable to increase red blood cell production in response to hypoxia. Gene deletion studies established that GR facilitates stress erythropoiesis in mice by blocking maturation of erythroid precursors and inducing a limited self-renewal state.[101] Although clinical observations indicating that the GR ligand such as dexamethasone stimulates erythropoiesis have been available since 1961,[102,103] the precise role of GR in human erythropoiesis is still unclear. Murine GR is not polymorphic, whereas human GR (GR/NR3C1 located in the 5q31-32 region of chromosome 5 and deleted in 5q- syndrome) contains several single-nucleotide polymorphisms (SNPs).[104-107] Because of this genetic diversity, human cells may express more than 260 isoforms with slightly or greatly different biologic activities. The most studied isoform is GRα, an isoform similar to the murine GR. Alternative splicing between exon 3-4 generates GRγ, an isoform containing an additional arginine in the deoxyribonucleic acid (DNA)-binding domain that reduces the transactivation potential by half. An alternative splicing of exon 9 generates messenger ribonucleic acid (mRNA) encoding the dominant-negative GRβ isoform.[107] It is debatable whether an isoform with dominant-negative action similar to GRβ exists in mice.[105,108] It is generally accepted that responses to GR ligands depend on the signal transduction potential of the GR isoforms expressed by different cells and tissues. Studies in human nonerythroid cell types have identified that GR isoform expression predicts the variegation of cellular response to dexamethasone in vitro.[109-111] Recently clinicians have established important correlations between GR haplotype and variability in patients' responses to glucocorticoids and in the development of glucocorticoid resistance in several disorders.[112] GR polymorphism and/or epigenetic changes are emerging as the leading cause for dexamethasone unresponsiveness or for development of dexamethasone resistance in patients with inflammatory and autoimmune diseases[113] (i.e., Crohn disease, systemic lupus) and in chronic depression.[112,114-116]

Similarly, several in vitro and in vivo studies suggest that variegation of GR isoform expression may also have biologic and clinical effects on terminal erythroid maturation. The numbers of erythroblasts generated by murine erythroid progenitors in response to dexamethasone is fairly consistent, whereas the number generated by human erythroid progenitors from different individuals may vary by 1 to 2 logs,[43,117] likely reflecting the genetic background of human GR. In addition, the frequency of the rs6198 SNP is greater than normal in patients with polycythemia vera (PV) (55%, $P = 0.0028$)[118] and with Diamond-Blackfan anemia (DBA) (43%, $P = 0.03$),[118] suggesting that genetic conditions favoring GRβ expression may represent host genetic modifiers in diseases with altered terminal erythroid differentiation.

The morphologic alterations that occur as erythroid precursor cells mature (see Fig. 24-2) are determined by complex biochemical changes, which accommodate the accumulation of erythroid-specific proteins and the progressive decline in proliferation.[119] Compared with erythroid progenitor cells, erythroid precursor cells have been more accessible to study, and considerable information is available about their maturation-related biochemical changes.

The shape and deformability of the red cells are determined by the appropriate assembly of their membrane proteins with the

cytoplasmic cytoskeleton. Red cells survive shear forces in the microvasculature because transmembrane complexes embedded in the lipid bilayer attach to the cytoskeleton, ensuring its flexibility. These complexes contain clinically relevant blood group antigens determined by genetic polymorphisms in proteins of these complexes.[120-122] The similarity between the amino acid sequence of the blood group antigens and that of proteins present on the surface of bacteria and the increased frequency of certain blood group antigens in regions with high incidence of malaria suggest that blood group antigens, in addition to ensuring appropriate membrane structure, may facilitate development of appropriate immunoreactivity toward opportunistic infections.

Most membrane cytoskeletal proteins (spectrin, glycophorin, band 3, band 4.1, and ankyrin) accumulate after the CFU-E stage (i.e., within the precursor cell compartment). Specifically, expression of membrane glycoproteins such as band 3 and band 4.1 is greatly enhanced at the later stages of erythroid maturation.[119,123,124] Likewise, the quantity of polylactosaminoglycan, a specific carbohydrate chain that carries blood group ABH and Ii antigenic determinants, is much higher in mature erythrocytes than in erythroblasts.[125] Whereas a linear, virtually unbranched polylactosamine structure is present in fetal and newborn erythroid cells (reflected by i antigenic reactivity), a branched polylactosaminyl structure is present in adult erythroblasts (reflected by I antigenic reactivity), and branching increases further as maturation progresses.[125,126] A correctly assembled cytoskeleton is important for the deformability and dynamic plasticity of red blood cells in circulation. A recently recognized player required for actin assembly in red cells, Rac GTPase, has been identified.[127] Glycophorins, especially glycophorin A, are expressed fully at the CFU-E or proerythroblast level just before expression of globin, and few changes occur during maturation.[46] In contrast, the membrane glycoproteins p105 and p95 decline during the later stages of maturation,[125] and yet other membrane glycoproteins, such as vimentin (an intermediate filament protein), are totally lost.[119] Loss of vimentin expression at the late erythroblastic stages most likely facilitates enucleation.

The process of erythroblast enucleation involves membrane remodeling,[128] chromatin condensation to form pyknotic nuclei, and formation of spindle independent motors driving the separation of the reticulocyte from the pyrenocyte (the pyknotic nuclei surrounded by a cytoplasmic rim).[129] Partitioning of erythroblast plasma membrane components to reticulocytes is regulated by the degree of skeletal linkage,[130] whereas chromatin condensation is mediated by the histone deacetylase (HDAC) 2,[131] suggesting that impairment of HDAC2 activity may contribute to the development of anemia observed in HDAC-based cancer treatments. Nonmuscle myosin appears to represent the motor driving the separation between the reticulocyte and the pyrenocyte.[132] Reticulocytes are released in the blood, where they undergo extensive cytoplasmic remodeling to reduce the number of ribosomes and mitochondria and to become mature red cells. This process is mediated by autophagic machinery,[133] whereas engulfment of pyrenocytes, and subsequent degradation by macrophages, occurs only after pyrenocytes are totally disconnected from reticulocytes. Phosphatidylserine, the "eat me" flag for apoptotic cells, is also used for engulfment of pyrenocytes expelled from erythroblasts,[134] whereas expression of CD47, the "eat me not" signal, by interacting with SIRP1α expressed by the macrophages, prevents engulfment and destruction of erythroblasts and reticulocytes.[135] The enucleation process is caspase independent[136] but erythroblast macrophage protein dependent.[137] Erythroblast macrophage protein is expressed by both erythroblasts and macrophages, and it is necessary for proper enucleation to occur.[137] The fact that proper enucleation requires interaction with macrophages explains the old observation that erythroid differentiation in the marrow occurs in discrete sites, the "erythroblastic islands," which are composed of erythroblasts surrounding a central macrophage.

In addition to quantitative changes that occur during maturation, gradual switches in subunit composition of some cytoskeletal proteins occur. For example, exclusively erythroid subunits of α- and β-spectrin are displayed only in end-stage cells.[50] Likewise, multiple transcripts of ankyrin or protein 4.1 have been identified, and the ratios of these transcripts change during maturation.[138] Initial expression of many of these membrane components likely begins at the progenitor cell level. However, in these cells, final assembly may be discouraged because of the higher turnover of these proteins, which minimizes mutual interactions, or because of asynchrony in protein synthesis. Prevention of cytoskeletal assembly at these early stages may secure more membrane fluidity and cell motility needed during this proliferative phase of differentiation. Because molecular probes for many of the red cell cytoskeletal components have been developed, detailed information about the transcription and processing of most of these proteins is beginning to emerge.[124] For example, band 3, the major anion transport protein of human erythrocytes, is a key component of a multicomplex that also contains protein 4.2. Appropriate display of this protein complex on the cell membrane is dependent on critical interactions established between newly synthesized band 3 and protein 4.2 already at the proerythroblast stage.[139]

Expression of the majority of genes encoding cytoskeletal components is not restricted to red cells. Dissecting hemopoietic from nonhemopoietic consequences of abnormalities in these genes has been difficult, but the development of mouse models that mimic defects found in human diseases has been helpful in this respect.[140]

Gene activity during erythroid maturation is dominated by globin expression. Globin represents less than 0.1% of protein at the proerythroblast level but constitutes 95% of all protein at the reticulocyte level.[141] Globin expression has been extensively studied, and its gene regulation is well understood in molecular terms. Major steps in globin transcription and processing are known in considerable detail and are summarized elsewhere in this text (see Chapter 31). The globin type synthesized by adult precursors is hemoglobin A (HbA; $\alpha_2\beta_2$). In addition, two other minor globin components, HbA_2 ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), are present. Of significant biologic interest are the low amounts of HbF that continue to be synthesized throughout life.

The small amount of HbF, which is present in all normal individuals, has the following characteristics.[142] (1) It is confined to a small fraction of red cells, called *F cells*, which are detected by sensitive immunofluorescence assays or acid elution techniques and usually constitute 2% to 5% of all red cells. Within each F cell, HbF or γ-globin constitutes 14% to 25% of total globin. (2) The number of F cells is genetically determined, and the gene(s) linked or nonlinked to the β-locus is responsible for F-cell formation. (3) F cells do not display other features of "fetalness" because their membrane components and enzymes are characteristically adult. (4) Synthesis of HbF peaks earlier than that of HbA, so the proportion of HbF is higher in immature cells compared with mature, fully hemoglobinized cells. (5) F cells and cells that contain only HbA are not derived from distinct stem cell populations but from a common adult stem cell. Whether the latter will form F or non-F (i.e., A) cells is determined at the BFU-E level and throughout the CFU-E level.[143] In vitro the great majority of BFU-E have the potential to express HbF, whereas in vivo only a very small proportion of red cells contain HbF. This potential appears to be lost during normal cell differentiation and maturation in vivo. This concept links the potential for HbF expression to the pathway of erythroid differentiation and thus may have implications for interpreting the reactivation of HbF that occurs in adults under diverse circumstances (e.g., after chemotherapy or with acute bleeding).[142] Many of these circumstances seem to influence HbF levels by directly or indirectly modifying the kinetics of the normal differentiation/maturation process.[144,145] HbF levels in red cells can be increased by exposing the cells during maturation to chemical inhibitors of HDAC. This class of enzymes nonspecifically suppresses gene transcription by catalyzing histone deacetylation and consequently chromatin condensation.[146] Therefore they can directly activate transcription of γ-globin genes in vitro and in vivo[147-149] and in a number of patients with β-thalassemia.[150,151]

Synthesis of globin appears to be coordinated with synthesis of heme throughout erythroid maturation so that functional hemoglobin tetramers are formed rapidly and spontaneously after release of newly synthesized globins from polysomes. Information about the accumulation of heme and its synthetic intermediaries has been

provided by crude biochemical approaches (see Fig. 24-2). However, now that the genes for several enzymes in the heme synthetic pathway (e.g., δ-5-aminolevulinic acid synthase, porphobilinogen deaminase, ferrochelatase) have been cloned, information about their regulation is rapidly emerging.[65,67]

An important role in coordinating heme and globin chain assembly during hemoglobin production is exerted by α-hemoglobin-stabilizing protein (AHSP). AHSP is a protein abundantly expressed in erythroid cells[152] whose function is to bind free α-chains, stabilizing their structure and limiting their ability to participate in chemical reactions that generate ROS.[153,154] In addition, AHSP binding increases the affinity of α-chains for β-chains, accelerating the formation of Hb tetramers. The essential role exerted by this gene in erythroid development has been demonstrated by the fact that its deletion in normal mice impairs red cell production. AHSP^{null} red cells have a decreased half-life, contain Hb precipitates, and exhibit signs of oxidative damage.[152] The observation that double AHSP^{null} β-thalassemic mutant mice have an exacerbated phenotype[155] suggests that AHSP is a gene modifier that, like the hereditary persistence of HbF mutations, ameliorates the phenotype of thalassemic patients. However, the search for AHSP polymorphisms that might correlate with milder clinical phenotypes in thalassemia has not provided consistent results. Gene mapping, direct genomic sequencing, and extended haplotype analysis did not reveal any mutation or specific association between haplotypes of AHSP in 120 β-thalassemic patients.[156] On the other hand, a polymorphism in the putative AHSP promoter leading to a threefold higher expression of the gene in reticulocytes has been observed in the normal population,[157] but the clinical consequences of this observation are unknown.

Crucial to the functional response of erythroid precursors is the expression of EPORs and TfRs. EPORs decrease progressively (from approximately 1000 to <300 receptors per cell) as proerythroblasts mature, and they are undetectable at the reticulocyte level.[59,158] Through these receptors, EPO exerts its proliferative influence on proerythroblasts and basophilic erythroblasts, but maturation beyond these stages can proceed in the absence of EPO.

TfRs are found in characteristic abundance in erythroid cells (300,000 to 800,000 TfRs per cell).[159] This composition reflects not only the proliferative needs of erythroid cells but also their extreme requirements for iron uptake for hemoglobin synthesis. For this reason, TfRs persist in maturing nondividing erythroblasts and in reticulocytes. TfRs belong to a large group of receptors that internalize their ligand through receptor-mediated endocytosis. This cycle allows for reuse both of the ligand (transferrin) for resaturation with iron and of the receptor for entering another route of endocytosis.[160] TfRs' density decreases with maturation. After the reticulocyte stage, receptors appear to be shed as small lipid vesicles.[161] An inverse relationship exists between receptor density and iron availability. Deprivation of iron results in receptor induction, and excess iron results in receptor suppression.[160] However, the mechanisms that regulate the number of TfRs throughout the maturation of precursors (even within progenitors) are largely unknown. Erythroid precursor cells differ from nonerythroid cells not only by requiring a higher number and higher occupancy of TfRs, but also by displaying immunologically distinct receptor isoforms.[64] A second gene for transferrin receptor (TfR2) has been identified,[162] and monoclonal antibodies recognizing distinct receptor isoforms are useful in isolating erythroid cells from bone marrow.[64,163] TfR1 and TfR2 are members of a family of genes encoding at least seven different homologous proteins in primates.[164] TfR1 is a type II membrane glycoprotein that, as a cell surface homodimer, binds iron-loaded transferrin as part of the process of iron transfer and uptake. TfR2 is expressed in two forms—membrane-bound (TfR2-α) and nonmembrane (TfR2-β)—both of which bind transferrin with low affinity. The specific role of TfR2 in hematopoietic cells is unclear. In cells from 67 patients with de novo acute myeloid leukemia (AML), high levels of TfR2-α expression were correlated with better prognosis, and higher levels of both TfR2-α and TfR2-β were associated with longer survival, suggesting that TfR-independent iron uptake plays a role in in vivo proliferation of AML cells.[165] TfR2 plays its most prominent role in the liver[166] as the key regulator of iron metabolism. Maintenance of stable extracellular iron concentrations requires the coordinate regulation of iron transport into plasma from dietary sources in the duodenum, recycled senescent red cells in macrophages, and storage in hepatocytes. Diferric transferrin is present in the liver due to complex machinery involving the product of the hereditary hemochromatosis (HFE) gene (a protein of the major histocompatibility complex class I), TfR2, and the product of the hemojuvelin (HJV) gene (also known as HFE2). Given that the levels of TfR2 expression are exclusively regulated by holotransferrin, TfR2 expressed by hepatocytes likely is the first element of the iron sensory pathway in the liver.[167] Hepatocytes respond to iron sensoring by modulating hepcidin expression and secretion. Hepcidin, a 25–amino acid disulfide-rich peptide, acts as a systemic iron regulatory hormone that regulates both dietary iron absorption by the enterocytes and iron recycling by the macrophages. Because ferroportin shuttles iron from the enterocytes to the macrophages and hepcidin is required for ferroportin internalization and degradation, decreased hepcidin expression blocks iron export in the two cell types.[168] Each gene involved in iron metabolism has a role in regulating the expression of the other genes. In particular, reduced expression of HEF, TfR2, and HJV reduces expression of hepcidin. It is not surprising then that mutations altering the function of all of these genes have been found to be associated with hereditary hemochromatosis. The most prevalent form of hereditary hemochromatosis (type 1; HFE1) involves mutations in HFE.[169] Most families with juvenile hemochromatosis (HFE2) have mutations in the HJV gene.[170] Homozygous nonsense[171] and single-point mutations causing methionine→lysine substitution at position 172 of the protein M172K[172] have been detected in the gene encoding TfR2 in patients with familial hemochromatosis HFE3. Autosomal dominant iron overload is associated with previously unrecognized ferroportin 1 mutations (p.R88T and p.I180T)[173] and with mutations in the divalent metal transporter 1 gene DMT1, which mediates apical iron uptake in duodenal enterocytes and iron transfer from the TfR endosomal cycle into the cytosol in erythroid cells.[174] The observation that targeted deletions of any of these genes (including TfR2) induce a hemochromatosis-like syndrome in mice provides proof of direct involvement of the mutations in disease development.[175-178] On the other hand, the finding that hepcidin is a gene modifier of the HEF^{null} mouse model of hemochromatosis suggests that heterogeneity at the hepcidin locus mediates the low penetrance of the genetic disease.[179] In addition to its role in determining the pathobiology of hereditary hemochromatosis, hepcidin plays an important role in determining the anemia of chronic diseases. Based on the central involvement of hepcidin in iron regulation and its pathologic conditions, a hepcidin assay has been proposed as a useful tool for diagnosing iron disorders and monitoring their treatment. On the other hand, development of hepcidin agonists and antagonists may provide useful therapeutics for treatment of iron disorders.[180]

The patterns of TfR and glycophorin A expression during erythroid maturation have been exploited to define flow cytometric criteria that distinguish the different populations of erythroid precursors in mice and men. By coupling size and forward scatter (both progressively reduced) with CD71 (TfR) and TER-119, murine erythroid precursors were divided into the classes TER-119^{med}CD71^{high}, TER-119^{high}CD71^{high}, TER-119^{high}CD71^{med}, and TER-119^{high}CD71^{low}, which correspond to proerythroblasts and basophilic, chromatophilic, and orthochromatophilic erythroblasts, respectively.[95] However, such distinction is not conserved in all mouse strains. For example, in C57Bl/6 mice, CD71 expression levels remain constant during maturation.[181] CD44/glycophorin A expression provides a better flow cytometric definition of the maturation stage of murine erythroblasts.[182] Unfortunately, maturation of human erythroblasts is not associated with significant changes of CD44 expression. Double CD71/glycophorin A staining is therefore still used as criteria to define human erythroblast precursors by flow cytometry. However, the pattern of CD71 expression during erythroid maturation presents a high level of donor variability. Given that downmodulation of CD36 expression during erythroid maturation is relatively independent of genetic variability, an alternative flow cytometric definition

of erythroblast subclasses is proposed by the phenotype $CD36^{high}$/glycophorin A^{medium}, $CD36^{high}$/glycophorin A^{high}, and $CD36^{low}$/glycophorin A^{high}, corresponding to basophilic, polychromatic, and orthochromatic erythroblasts, respectively.[183] Flow cytometric criteria for reticulocytes and red cells are instead provided by size (reticulocytes and red cells are distinctively smaller than erythroblasts) and by lack of reactivity for DNA (both reticulocytes and red cells) and RNA (reticulocyte only) staining.

ERYTHROPOIETIN AND EPOR

EPO, a 35-kd glycoprotein,[184] is the physiologically obligatory growth factor for erythroid development. It is produced mainly in the kidney by peritubular cells.[185] A heme-containing protein senses oxygen need and then triggers the synthesis of EPO and its release into the bloodstream.[186,187] Through the interaction of EPO with receptor-bearing cells within the bone marrow, physiologic oxygen demands are translated into increased red cell production. Thus EPO is a true hormone, manufactured at one anatomic site and transported through the bloodstream to the site of activity.

According to the prevailing model of hematopoiesis, progenitor cells committed to erythroid differentiation (i.e., BFU-E) are generated in a stochastic fashion from pluripotent stem cells.[4,5] Neither EPO nor other lineage-restricted regulators play any role in determining lineage commitment. According to this model, EPO influences erythroid differentiation by rescuing (from apoptosis) cells that express EPOR and amplifying them further. Whether EPORs are present on all BFU-E (detectable only in a subset of BFU-E) is not clear.[61] Thus whether the presence of EPOR in BFU-E is synchronous with the initial commitment event or follows it is not known. In addition to the permissive role of EPO ascribed by the stochastic theory, experiments in vivo, in anemic states, or after pharmacologic doses of EPO suggest that high levels of EPO hasten the transition from BFU-E to hemoglobin-synthesizing cells by decreasing either the number of divisions required for this transition[90] or the resting periods between cell divisions.[188] Autoradiographic studies of purified BFU-E populations indicate that EPORs increase as BFU-E mature to CFU-E, with the highest level observed at the CFU-E/proerythroblast boundary.[61] That the transition from BFU-E to CFU-E occurs under the influence of EPO suggests ligand (EPO)-induced receptor upregulation. Whether the magnitude of such upregulation is dependent on EPO dose and whether it can modulate the rate of entry of these cells into the maturing compartment is unclear.

BFU-E and CFU-E can be generated in vitro[189] and in vivo,[190] in the absence of EPO or EPOR (in EPO or $EPOR^{null}$ mice), but their survival and terminal maturation normally are dependent on EPO. For CFU-E, EPO seems to stimulate all the biochemical processes characterizing erythroid cells (i.e., heme synthesis, globin synthesis, and synthesis of cytoskeletal proteins). However, the necessity of EPO in these processes is not absolute. In vitro experiments showing complete maturation of BFU-E in the absence of EPO suggest that other factors or combinations of factors can influence red cell maturation. Activation of the gp130 signaling pathway by use of soluble IL-6 receptor and IL-6 leads to full terminal erythroid maturation (in the presence of stem cell factor and IL-3 but in the absence of EPO), suggesting some form of cross-circuiting in signaling pathways among hematopoietic growth factor receptors.[191,192] Furthermore, stimulation by TPO of erythroid colony formation from yolk sac cells in the absence of EPOR (in $EPOR^{-/-}$ embryos)[193] can be explained by the same reasoning and the finding of a very high proportion of bipotent erythroid/megakaryocytic progenitors in yolk sac carrying both EPO and TPO receptors (c-Mpl) compared to adult bone marrow.[56,194,195]

Whatever the precise mode of EPO action, it directly affects the number of CFU-E and the maturation of their progeny. This control is achieved by influencing CFU-E survival and not their cycling status.[196] CFU-E are irrevocably lost after one cycle of DNA synthesis if EPO is not present.[197]

With the availability of radiolabeled recombinant EPO and purified or enriched populations of progenitors and precursors has come information about the characteristics of EPORs in erythroid cells. Direct binding studies have shown that a progressive decrease in the number of EPORs occurs as CFU-E and proerythroblasts mature to reticulocytes.[60,61,158] Pure reticulocyte populations show no detectable binding to EPO. The maturation-associated decline in the number of EPORs parallels the declining influence of EPO on erythroid cells during the terminal phase of maturation. The exquisite role of EPO in determining red cell numbers in the circulation has been clearly established by direct correlations between hematocrit and EPO plasma concentrations in individuals exposed to hypoxia and in patients with compromised kidney functions.[198] However, the variabilities around the mean of hematocrit and EPO plasma levels found in normal individuals under steady-state conditions are not correlated, indicating that other factors (sex and age) cooperate with EPO in determining the fluctuations in red cell mass under steady-state hematopoiesis.[199]

Cloning and expression of EPOR has allowed for a better understanding of the role of EPO in the regulation of erythroid development. The EPOR polypeptide is a 66-kd membrane protein that is a member of the cytokine receptor superfamily.[200,201] Many of the structural features of the cell surface EPOR have been previously reviewed.[202] Like other members of the cytokine receptor superfamily, which includes the receptors for IL-3, GM-CSF, and IL-5, the EPOR polypeptide contains four conserved cysteine residues and a WSXWS motif in the extracellular region. Additional extracytoplasmic sequences of EPOR determine the specificity for EPO binding. The cytoplasmic region of EPOR does not contain a tyrosine kinase catalytic domain; instead it interacts with cytoplasmic tyrosine kinases. Cross-linking of radiolabeled EPO to cell surface EPOR results in formation of at least two major cross-linked protein complexes of 140 and 120 kd.[203] The molecular composition of these complexes remains unsolved but suggests that EPOR contains additional subunits or accessory proteins.[204] The extracytoplasmic region of the EPOR polypeptide contains the EPO binding activity of the receptor.[205-207] Therefore additional EPOR subunits may provide other structural and functional elements of the receptor but are not required for high-affinity EPO binding. The extracytoplasmic region of the EPOR polypeptide has been crystalized.[208-210] The crystal structure confirms the dimeric structure of the activated receptor. Interestingly, small synthetic peptides are capable of inducing EPOR dimerization, suggesting a profitable avenue for EPO-mimetic and EPO-antagonist drug design.[211] EPO-mimetic agents are represented by polypeptides restricted to the portion of the protein that binds the receptor, by forms of the protein molecularly engineered to increase its glycosylation state and therefore its stability in vivo, or by dimeric forms of proteins obtained by genetic introduction of bridging sites or chemical cross-linking.[212] It also is possible that nonpeptide chemicals sharing the same stereo and electric properties of the receptor-binding domain of the protein might be identified. As shown for carbamylated EPO, modified isoforms may have biologic activity that partially differs from, and is possibly more effective than, the native protein,[213] especially with regard to the activity of the growth factor in nonhematopoietic tissues.[214]

EPOR mRNA, originally isolated from murine erythroblast cell lines (MEL and HCD57)[184] and from a human erythroid cell line (OCIM1),[215] has been found in nonerythroid cells as well. EPO promotes the differentiation of megakaryocytes at physiologic concentrations of hormone, suggesting that megakaryocytes have functional cell surface EPORs. Rat and mouse placenta also have cell surface EPOR, detected by radiolabeled EPO cross-linking. EPO promotes a chemotactic effect on endothelial cells,[216,217] suggesting the presence of a cell surface receptor in these cells. Other studies suggest that EPOR is expressed in neural cells[218] and smooth muscle cells.[219] Adverse effects in cancer patients treated with EPO have been attributed to the effects of EPO on tumor cells.[220] The functional importance of EPOR expression in nonerythroid cells has been revealed by rescue experiments in $EPOR^{null}$ mice.[221] Because $EPOR^{null}$ mutant mice die of severe anemia between days 13 and 15 of embryonic development, the mutant embryos can be rescued by transgenic expression of EPOR under the control of the hemopoietic-specific

GATA1 regulatory domain. Under steady-state conditions, the rescued animals are normal, because the gene is expressed only in erythroid cells. However, in comparison with normal mice, the increase in plasma EPO concentration in response to induced anemia was delayed in the rescued animals, suggesting that one of the major functions of EPOR expression in nonerythroid cells is fine-tuning the regulation of the response to stress.[221]

The existence of naturally occurring splice variants of the EPOR gene encoding EPOR polypeptides of variable length and activity has been shown.[222-225] The soluble secreted form of EPOR[226] binds EPO and thereby competes with the cell surface receptor isoform. The biologic function of alternative forms of the cell surface EPOR, including a truncated form of EPOR found in early progenitors,[227] remains unknown but may be related either to differential EPO signaling and responses (survival, proliferation, differentiation) at different stages in erythroid development or to the establishment of erythroid-specific versus myeloid-specific niches in the marrow microenvironment.

SIGNAL TRANSDUCTION BY EPOR

Considerable progress has been made in our understanding of EPOR-mediated signal transduction. Early studies demonstrated that stimulation of EPOR on primary erythroid cells resulted in increased calcium ion flux and increased globin mRNA synthesis.[228] Since the cloning of the EPOR polypeptide and its stable expression in heterologous cell systems, such as the Ba/F3 cell system,[229] considerable molecular insight has been gained.[230] For instance, it now is clear that EPO induces homodimerization of the EPOR polypeptide.[231,232] Following receptor dimerization at the cell surface, a series of tyrosine phosphorylation events occurs, resulting in a mitogenic signal and a differentiative signal.[233,234] Initial studies of the EPOR signal transduction pathway made use of mutant forms of EPOR stably expressed in the indicator cell line Ba/F3. Ba/F3 cells are a murine IL-3–dependent pro–B lymphocyte cell line. These cells can be readily transfected with the complementary DNA (cDNA) for EPOR, resulting in stable expression of the receptor on the cell surface. Expression of the full-length, wild-type EPOR polypeptide in these cells resulted in EPO-dependent growth and partial EPO-induced erythroid differentiation.[233,234] Expression of truncated forms of the EPOR polypeptide in these cells resulted in variable growth responses. For instance, truncation of the membrane proximal region of EPOR demonstrated a critical positive regulatory domain of EPOR required for mitogenesis.[229] Furthermore, truncation of the carboxy-terminal 40 amino acids of EPOR resulted in increased EPO-dependent growth, suggesting that the carboxy-terminal region contained a negative regulatory domain normally required for downmodulating EPOR mitogenic signals.[229]

The biochemical basis for these positive and negative regulatory domains has been elucidated. The membrane proximal positive regulatory region of EPOR binds constitutively to Janus-activated kinase 2 (JAK2),[235] a cytoplasmic tyrosine kinase necessary for erythroid differentiation, as evidenced by mice lacking the corresponding gene dying at an early embryonic stage.[236] Upon EPO binding to the receptor, the receptor dimerizes, resulting in activation of prebound JAK2. The JAK2 next tyrosine phosphorylates multiple signaling proteins in the cell, leading to various mitogenic and differentiative responses. The negative regulatory domain of EPOR is required for recruiting the phosphatase SHP1 to EPOR.[237] SHP1 binds to an activated tyrosine phosphate on the EPOR polypeptide and rapidly downregulates JAK2 activity and dephosphorylates the EPOR polypeptide. Failure to recruit the SHP1 phosphatase can result in increased EPOR signaling and a polycythemic state (see Alterations in EPOR and Its Signaling in Disorders of Erythropoiesis).

JAK2 is required for appropriate Golgi processing and cell surface expression of EPOR.[238] Once activated by EPO/EPOR binding on the cell surface, JAK2 initiates several events in EPOR-mediated signal transduction. JAK2 initially activates tyrosine phosphorylation of several tyrosine residues of the cytoplasmic tail of EPOR. These phosphorylated tyrosine residues next serve as docking sites for binding of other cytoplasmic effector proteins containing Src homology 2 (SH2) domains, such as the p85 subunit of phosphatidylinositol 3-kinase,[239] the adaptor protein Shc,[240,241] and STAT5.[242,243] (Examples of signal transduction proteins expressed in primary human erythroblasts are given in Table 24-2). Once these proteins have docked on EPOR, they become tyrosine phosphorylated and engage other downstream signaling events. In addition, JAK2 activates the Ras/Raf/MAPK (mitogen-activated protein kinase) pathway, further contributing to the EPO-induced mitogenic signal.[244,245] The molecular mechanism of Ras activation by JAK2 remains unknown but may entail direct binding of the proteins and tyrosine phosphorylation.[245]

Activation of the JAK2/STAT5 signaling pathway has been studied in considerable detail. Upon EPOR tyrosine phosphorylation, STAT5 protein binds to a specific phosphorylated tyrosine residue of the EPOR.[242,246] Binding is mediated by the SH2 domain of STAT5. Following EPOR binding, STAT5 itself becomes tyrosine phosphorylated at amino acid Y694.[247] Activated STAT5 then disengages from EPOR, undergoes homodimerization, and translocates to the cell nucleus, where it activates transcription of EPO-inducible genes. Some EPO-inducible genes, such as MYC and FOS, are common to other hematopoietic growth factor signaling pathways. Other EPO-inducible genes are specifically expressed in erythroid cells and are not shared by other growth factor responses.[248]

Other signal transduction pathways downstream from cytokine receptors have been identified. For instance, EPO and IL-3 activate tyrosine phosphorylation of the signaling protein CBL and the subsequent binding and tyrosine phosphorylation of the signal protein CrkL.[249] The mechanism of activation of this pathway by EPOR is not known, and the relative role of this pathway in EPO-induced growth and erythroid differentiation remains largely unexplored. Inositide-specific phospholipases C (PLCs) and the protein kinase C (PKC) pathway also are involved in EPO signaling. PLCs catalyze hydrolysis of phosphatidylinositol 4,5-bisphosphate to generate diacylglycerol and inositol 3,4,5-bisphosphate, a well-known intracellular messenger for PKC activation and intracellular Ca^{2+} mobilization. PLCs are classified into four isoform families (α, β, γ, and δ), and each family has multiple isoforms.[250,251] The involvement of PLCs in erythroid differentiation was suggested by early studies demonstrating that stimulation of EPOR in primary erythroid cells results in increased calcium ion flux.[228] More recent studies demonstrated that primary erythroblasts express only some (i.e., PLC β_1, β_2, β_3, δ_1, γ_1, and γ_2) PLC isoforms. Among these, PLCβ_1 most likely is involved in EPO signaling, based on findings that its expression is induced within 6 hours of stimulation with the growth factor.[22,183,252] On the other hand, PKC represents a family of nine different serine-threonine kinases genes, encoding a total of 12 different isoforms, involved in the regulation of many cellular functions.[253] These enzymes exert their biologic functions as a cytoplasmic-nuclear shuttle of the transduction machinery and become phosphorylated, and hence activated, in response to a variety of stimuli. Human multipotent $CD34^+$ progenitor cells express all of the PKC isoforms.[254,255] Commitment of these cells along the erythroid lineage requires suppression of PKCε.[254,256] PKCε exerts a positive control on erythropoiesis, because its inhibitors specifically impair the ability of erythroid cells to respond to EPO[257] and to phosphorylate EPOR, STAT5, GAB1, ERK1/2, and AKT.[258] It also is possible that different PKC isoforms are active at different ontogenic stages, because PKCα and PKCδ are differentially phosphorylated, and hence activated, during differentiation of neonatal and adult erythroblasts.[259]

EPO signaling activates also Lyn, a tyrosine kinase member of the Src family[260] physically associated with EPOR.[261] Lyn acts upstream to both the STAT5[261] and the PLCγ_2/PI3K pathways.[262] Failure to activate Lyn prevents erythroid differentiation of the J2E cell line[260] and Lyn^{null} mice have a phenotype remarkably similar to that of $GATA1^{LOW}$ mice (normal hematocrit in spite of reduced levels of GATA1, erythroid Krüppel-like factor (EKLF), and STAT5 expression due to development of extramedullary hematopoiesis in spleen).[263] In addition to STAT5 and PLCγ2/PI3K signaling, Lyn activates Liar,

Table 24-2 Major Transcription Factors/Signaling Molecules Involved in the Control of Erythropoiesis

Transcription Factor	Binding Motif	Role in Hematopoiesis	Knock-Out Phenotype	Mutations/Human Disease
GATA1	(A/T)GATA(A/G)	↑ Erythroid differentiation	• No terminal erythropoiesis • Arrest in Mk development (with hyperproliferation)	• X-linked thalassemia/ thrombocytopenia • Leukemia (Down syndrome)
GATA2	(A/T)GATA(A/G)	↑Proliferation ↓Differentiation	↓ Proliferative expansion of primitive and definitive erythropoiesis Absence of mast cells	MonoMAC syndrome, MDS, AML
FOG-1	None	GATA1 cofactor	↓ Erythroid maturation Block in megakaryocyto poiesis	
EKLF	CACCC	Promotes terminal erythroid differentiation	Severe anemia β-globin deficiency	β-Thalassemia, Lu-negative blood phenotype, HPFH, Nan phenotype in mice
SCL	CANNTG (E-box)	Specification of hematopoiesis	Absence of prenatal hematopoiesis ↓ Erythro/Mk in adults	Translocation in T-cell ALL
LMO2	LIM domain		Absence of hematopoiesis	T-cell ALL
Myb	(T/C)AAC(G/T)G	↓ Definitive erythropoiesis	Block in definitive erythropoiesis	HPFH, Myb-GATA1 fusion gene in acute basophilic leukemia
Fli-1	Winged helix-turn-helix	Inhibition of GATA1 expression		
BKLF	CACC		Myeloproliferative disorder	
SHP1 (BKLF activated?)				Erythroleukemia Polycythemia vera
STAT5	GAS		Transient fetal anemia due to apoptosis of erythroid progenitors Mild anemia, exacerbated by stress in adult life	
PU.1	GGAA	↓ Erythropoiesis	Absence of myelomonocytic differentiation	
Id		Blocks terminal differentiation of all cell types		
IaPI-3 kinase (p85)		↓ Proliferation/differentiation	↓ Fetal erythropoiesis Perinatal death	
Gfi-1b	Zinc finger domain	↑ Proliferation (↑ GATA2)		
Sp3			↓ Fetal erythropoiesis Perinatal death	
NF-E2	TGAGTCA	Promotes terminal erythroid differentiation in vitro	Thrombocytopenia Absence of erythroid abnormalities (?)	

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *BKLF,* basic Krüppel-like factor; *EKLF,* erythroid Krüppel-like factor; *FOG-1,* Friend of GATA1; *HPFH,* hereditary persistence of fetal hemoglobin; *LMO2,* LIM domain only 2; *MDS,* myelodysplastic syndrome; *SCL,* stem cell leukemia; *↓ Erythro/Mk,* decrease in erythropoiesis/megakaryocytopoiesis.

a Lyn-binding nuclear/cytoplasmic shuttling protein[264] specifically responsible for downregulating KIT expression in response to EPO.[265] In humans, Lyn is responsible for the phosphorylation of several membrane proteins, and failure to activate Lyn results in the formation of acanthocytic red cells, a diagnostic marker of chorea-acanthocytosis, a rare autosomal recessive neurodegenerative disorder.[266]

Erythroblasts generated under conditions of stress retain C-KIT expression. Several studies have investigated the relationship between KIT signaling and erythroid cell fate. In human and murine erythroid progenitors, KL induces rapid, within 15 minutes, ERK activation, which lasts only 1 hour.[267,268] In human erythroleukemic K562 and myeloid MO7e cells, the rapid KL-dependent ERK activation is associated with proliferation, whereas the late sustained ERK activation is responsible for differentiation.[269,270] Whether KL activates the STAT5 pathway in erythroid cells is controversial. Although KL was found to be unable to activate STAT5 in prospectively isolated human erythroid progenitor cells,[267] more recent single-cells fluorescence-activated cell sorter (FACS) analyses indicate that KL activates STAT5 in bipotent erythroid/megakaryocytic but not in myelomonocytic progenitor cells.[271] KL has also been described to activate the PI3K/AKT pathway in murine erythroid progenitors[268] and in human MO7e cells.[270] Finally, coexpression of KIT and EPOR deletion mutants in 32D cells have identified that KIT intracellular tyrosines play an essential role in EPOR cosignaling,[272] providing a mechanism for the signaling synergy observed between KL and EPO.

A critical question in the field of EPOR signal transduction is the mechanism of EPO specificity. Most, if not all, of the signal transduction pathways activated by EPOR (i.e., Ras/Raf/MAPK and JAK/STAT) are shared by other hematopoietic cytokine receptors, such as the receptors for IL-3, GM-CSF, and IL-5. How EPOR triggers a specific growth factor response resulting in erythroid differentiation

is unclear. Several models are possible. First, EPOR may activate unique but unknown signaling pathways specific to EPOR and distinct from other cytokine receptors. Alternatively, EPOR may activate identical pathways, activated by other cytokine receptors. In the latter model, the specificity of the EPO signal is derived not from EPOR itself but from interactions with other developmentally programmed events in the erythroid cell, such as expression of erythroid-specific transcription factors.

Activation of EPOR in the murine IL-3–dependent cell line Ba/F3 results in induction of both mitogenesis and globin accumulation.[158] In contrast, the murine IL-2–dependent cell line CTLL-2, when engineered to express the heterologous EPOR, grows in EPO but does not differentiate into globin-bearing cells. These data suggest that expression of EPOR is necessary for erythroid differentiation but not sufficient alone. Other erythroid-specific markers, such as GATA1 and NF-E2, or EKLF, likely are required for cells to differentiate down the erythroid pathway. Other cytokine receptors, such as IL-3R and IL-2R, do not drive β-globin synthesis in these cell lines. Taken together, these results suggest that EPOR generates a differentiation-specific signaling within the context of a proper transcriptional environment.

Regardless of the mechanism of cytokine specificity, each cytokine receptor activates a similar but not identical pattern of signaling events. For instance, EPOR shows a preferential activation of the JAK2/STAT5 pathway in cultured erythroid cells in vitro. In contrast, IL-2R shows preferential activation of the JAK1/JAK3/STAT6 pathway.[247,273,274] Interestingly, although EPO activates STAT5a and STAT5b in cultured cells, knockout of the STAT5a or STAT5b gene by homologous recombination results in a mouse phenotype with slightly impaired stem cell activity but apparently normal baseline erythroid development.[275,276] More extensive analysis of this phenotype has revealed that the mice experience increased apoptotic rates at erythroblast levels that are compensated by a cellular compensatory mechanism very similar to that described for GATA1^{LOW} mutants,[95] involving expansion of hemopoietic progenitors in the marrow and recruitment of the spleen as an additional hemopoietic site. These results suggest that, in vivo, other STAT proteins are at least partially capable of substituting for STAT5 and functioning downstream of the EPOR. These findings emphasize the importance of in vivo studies in confirming the phenotypic relevance of in vitro studies.

Studies have suggested that EPO functions synergistically with other multilineage growth factors, such as KL and IL-3. EPO and KL function together, resulting in increased erythroid colony cell growth in methylcellulose culture. Studies with the EPOR polypeptide suggest a molecular mechanism for such synergy.[277] Activation of the KIT receptor by KL results in transphosphorylation of EPOR at the cell surface. A direct interaction between EPOR and the KIT receptor has been demonstrated.[278] Physical interaction between EPOR and the β common chain of the IL-3 receptor in erythroid cells has been demonstrated.[279] This interaction might be involved in the neuroprotective action exerted by EPO.[280] In fact, a carbamylated derivative of EPO prevents motoneuron degeneration in vitro and in vivo[280] and ameliorates recovery in several in vivo models of brain and heart injuries, such as chronic autoimmunoencephalomyelitis in mice,[281] radiosurgery- or ischemia-induced brain injury,[282] and myocardium ischemia–reperfusion injury[283] in rats. (For a review of the nonhematopoietic activity of EPO, see reference 284) Taken together, these results suggest that receptor cross-talk at the cell surface may account, at least in part, for the physiologic interaction of some cytokines in controlling hematopoietic versus nonhematopoietic effects of EPO.

ALTERATIONS IN EPOR AND ITS SIGNALING IN DISORDERS OF ERYTHROPOIESIS

As discussed earlier, the normal role of EPO is to stimulate cell surface EPOR in developing erythroid cells. The latter cells respond to EPO via a proliferative and differentiation response. EPO-activated signal transduction of EPOR is quickly downregulated in the cell, and continuing presence of EPO is required for optimal differentiation.

In some cells, the EPOR may become constitutively activated. In these cases, erythroid progenitor cells are placed into a sustained proliferative state. Interestingly, these mechanisms underlie several murine and human examples of erythrocytosis (erythroid overproduction). Multiple mechanisms exist by which EPOR may become constitutively activated. First, the Friend spleen focus-forming virus of the Friend erythroleukemia complex encodes the glycoprotein F-gp55, which binds and activates murine EPOR.[285-287] F-gp55 appears to bind to EPOR via its transmembrane region. EPO and F-gp55 binding sites are discrete; tertiary complexes of EPOR, EPO, and F-gp55 have been detected on the surface of Friend virus-infected cells.[288] Second, EPOR can be constitutively activated by a point mutation (R129C) in the extracytoplasmic region of the polypeptide.[289] This mutation occurs in the "dimerization domain" of EPOR and results in constitutive homodimerization of the EPOR polypeptide, presumably through a disulfide bond. This mutation further underscores the importance of receptor dimerization in the initiation of a receptor signaling response. Third, EPOR can be constitutively activated in an autocrine manner. Murine erythroleukemia cell lines have been established that coexpress EPOR and EPO. A fourth mechanism of EPOR constitutive activation results from EPOR overexpression. For instance, some murine erythroleukemia cell lines have increased EPOR mRNA, resulting from spleen focus-forming virus proviral integration within the first intron of the murine EPOR gene.[290] Overexpression of the normal murine EPOR polypeptide may thereby contribute to oncogenesis.

Soon after the cDNA of mouse and human EPOR were cloned, the mouse and human genomic structures were identified. The gene for mouse EPOR was found to map to mouse chromosome 9,[291] whereas the human gene was found on human chromosome 19p.[292] Mapping of the EPOR genes led to their implication in various human disease states. For instance, studies demonstrated that a chromosomal breakpoint 3′ to the human EPOR gene results in increased EPOR expression.[293] The rearranged EPOR allele appears to encode a mutated EPOR polypeptide with increased activity, perhaps secondary to loss of the carboxy-terminal negative regulatory domain.

EPOR plays a role in the rare congenital disease familial erythrocytosis. Familial erythrocytosis is a heterogeneous group of hereditary conditions characterized by an increase in red blood cell mass in the setting of low serum EPO levels. A few families that demonstrate autosomal dominant inheritance have been identified.[294] The linkage between the EPOR gene and familial erythrocytosis was first established by the observation that a mutant EPOR allele segregates with the disease in one familial erythrocytosis kindred. This allele contains a nonsense mutation in the coding region of the gene that results in synthesis of a truncated EPOR that lacks the negative regulatory domain of its carboxy-terminal region.[295,296] Since that report, several other frameshift and deletion EPOR gene mutations, all encoding carboxy-terminal–truncated forms of the protein providing EPO hypersensitivity and resulting in familial erythrocytosis, have been reported.[297-301]

Congenital polycythemia may arise not only from gene mutations leading to abnormal EPOR signaling but also from gene mutations altering EPO production. The T598T mutation in one of the genes controlling oxygen sensoring (von Hippel-Lindau (VHL) gene), which leads to increased EPO production by the kidney, is associated with congenital erythrocytosis, the Chuvash polycythemia.[302,303] The C598T VHL mutation is endemic in Chuvashia, Russian Federation, and in the small island of Ischia, in southern Italy. The frequency of the mutation on this small island is higher than in Chuvashia (0.07% versus 0.02%), but the haplotype of Italian patients matches that identified in the Chuvash cluster, supporting a single-founder hypothesis.[304]

Acquired mutations in the EPOR signaling pathway have been identified in PV, essential thrombocythemia, and idiopathic myelofibrosis, a class of myeloproliferative neoplasm that lacks the

Philadelphia chromosome (Ph) abnormality and therefore cannot be cured with inhibitors, such as Gleevec, which are specific for the signaling pathway altered by the Ph abnormality. These diseases originate at the level of the pluripotent hematopoietic stem cell and are characterized by proliferation of one or more of the myeloid lineages but relatively normal hematopoietic cell maturation. Several investigators have reported a mutation in the JAK2 gene resulting in a valine→phenylalanine substitution at position 617 of the protein (JAK2V617F mutation) in patients with Ph-negative chronic proliferative disorders.[305-308] Since the early reports, the presence of JAK2V617F in patients with Ph-negative myeloproliferative disorders has been confirmed by numerous publications. Depending on the study, JAK2V617F has been reported in 60% to 90% of patients with PV, 30% to 50% of patients with essential thrombocythemia (ET), and 30% to 60% of patients with primary myelofibrosis (PMF). The mutation is harbored at either the heterozygous or, by somatic recombination, the homozygous stage. It is detectable in all myeloid cells up to the clonal hematopoietic stem cells.[309] The mutation affects the domain of the protein that is directly involved in signal transduction but is necessary to return the protein to its resting configuration after signaling. As a consequence, after its first engagement with EPO, EPOR signaling becomes constitutively activated. Because JAK2 is the earliest element of the EPOR pathway, it is conceivable that the high red cell numbers found in patients with PV carrying the JAK2V617F mutation is a direct consequence of constitutive EPO signaling in erythroid cells. The extent to which the downstream EPOR signaling pathway is altered as a consequence of this constitutive activation is a debatable issue. The observation that erythroblasts derived in vitro from patients with PV carrying the JAK2V617F mutation are highly resistant to TRAIL-induced apoptosis[310] suggests that the mutation exquisitely increases erythroblast survival. However, additional abnormalities induced by the presence of JAK2V617F are represented by hypersensitivity to insulin-like growth factor I[311] and increased EPOR recycling from the Golgi apparatus.[238] Therefore inhibitors directly targeting the JAK2V617F mutation might represent the best candidates for PV therapy. More difficult to understand is why the mutation is also present in some patients with ET and PMF. JAK2, in addition to EPOR, has an important role in transducing the signal from c-Mpl, the TPO receptor.[312] The protein has two opposing effects on the intracellular p rocessing of the two receptors after growth factor stimulation: it favors EPOR recycling from the Golgi apparatus,[238] but it determines retention and degradation of c-Mpl in the cytoplasm.[313] As such, the JAK2V617F mutation should increase the number of EPOR on the surface of erythroid cells while reducing that of c-Mpl on megakaryocytes. This hypothesis explains why the mutation is found preferentially in PV. However, megakaryocytes originating from JAK2V617F stem cells might express a reduced number but constitutively active c-Mpl, so it can be argued that the mutation manifests itself prevalently in the erythroid or the megakaryocytic lineage, depending on genetic polymorphisms outside the JAK2 locus present in the population. This hypothesis is supported by the observation that mice transplanted with JAK2V617F hematopoietic stem cells develop either a PV- or an ET–like syndrome, depending on their genetic background[314] and/or level of JAK2V617F expression.[315,316] One of the genetic factors that may determine the phenotype expressed by JAK2V617F-positive myeloproliferative neoplasms may be represented by the GR locus. The blood mononuclear cells from PV patients, but not those from ET or PMF, express increased levels of the dominant negative GRβ isoform. Increased levels of GRβ are also expressed by the erythroblasts expanded in vivo from PV patients. The observations that these erythroblasts lack nuclear STAT5 activity, in spite of constitutive STAT5 phosphorylation induced by the presence of JAK2V617F mutation, and do not mature in response to EPO[118] suggest that constitutive inhibition of the EPO maturation signal provided by GRβ expression may confer a self-renewal state to PV erythroblasts, contributing to erythrocytosis. Expression of GRβ may be favored by the increased frequency of the rs6198 SNP, which stabilize GRβ mRNA observed in these patients.[118]

Studies on the biology and biochemistry of the JAK2V617F mutation are actively being pursued by many investigators. Furthermore, in JAK2V617F-negative PV or idiopathic erythrocytosis patients, several other gain-of-function mutations affecting JAK2 exon 12 with a distinct phenotype (idiopathic erythrocytosis) have been identified.[317] The identification of specific mutations and the availability of the crystal structures of EPO, EPOR, and JAK2 should allow use of computer modeling to design targeted protein-signaling inhibitors for treatment of Ph-negative myeloproliferative neoplasms.[318]

HEMATOPOIETIC MICROENVIRONMENT

In invertebrates such as worms and sessile marine creatures, erythropoiesis occurs adjacent to peritoneal and endothelial cells. In premammalian species, the spleen is the primary site of erythropoiesis. With evolutionary advancement, the function gradually shifts to the liver and the sinusoidal cavities of bones.[9] These observations suggest that sufficient oxygen, a stagnated flow of blood to avoid dispersion of factors produced locally, and extensive and redundant surfaces for cell-cell interactions are essential to supporting red cell production. Similar sites support erythropoiesis during human development (see Ontogeny of Erythropoiesis). During both phylogeny and ontogeny, the liver and spleen are primarily erythropoietic organs; granulocytic cells dominate in the bone marrow.[9] Within the bone marrow, hematopoiesis is restricted to the extravascular space, where compact collections of cells are interspersed among venous sinuses. These sinuses originate adjacent to the endosteal bone surface and empty into a central longitudinal vein. Studies in mice demonstrate that BFU-E follow a bimodal distribution with peaks adjacent to the periosteum and midcavity, whereas CFU-E and later erythroid cells have a broad distribution with highest incidence toward the axis of the femur, adjacent to the central vein,[9,319] thus suggesting that the local anatomy (specialized niches?) influences the maturation of erythroid cells.

The bone marrow microenvironment consists of three broad components: stromal cells (e.g., fibroblasts, endothelial cells, mesenchymal stem cells and their diverse descendant progeny), accessory cells (monocytes, macrophages, megakaryocytes, T cells), and extracellular matrix (a protein-carbohydrate scaffold). In the bone marrow, although early studies described two distinct hematopoietic niches for hematopoietic stem cells /progenitor cells (i.e., the "endosteal" niche and the "endothelial or vascular niche" within the medulla), more recent studies suggest that this distinction may be artificial, because both cellular structures can be intimately associated in trabecular bone. Thus mesenchymal stem cell–derived osteoprogenitor cells and stromal reticular cells (nestin+ or leptinR+) are intimately associated with sinusoidal endothelium and seem to be pivotal organizers of the bone marrow niche.[320-322] Reciprocal communication of hematopoietic stem cells with cells/matrix in their bone marrow niche ensures both their quiescent state and self-renewal dynamics.

EPO, in addition to promoting erythropoiesis directly, enhances erythropoiesis indirectly by decreasing the interaction of hematopoietic stem cells with their niches, reducing the amount of trabecular bone[323] and downregulating CXCR4 expression, the receptor for CXCR12L/SDF1, on hematopoietic stem cells[324]).

Accessory cells are progeny of hematopoietic stem cells; hence after marrow transplantation these cells are of donor origin, whereas stromal cells remain mostly host derived.[325,326] Extracellular matrix molecules are synthesized and secreted by microenvironmental cells and include collagens (types I, III, IV, and V), glycoproteins (fibronectin, laminins, thrombospondins, hemonectin, and tenascin), and glycosaminoglycans (hyaluronic acid, chondroitin, dermatan, and heparan sulfate).[327,328] The production of extracellular matrix proteoglycans by mesenchymal stromal cells may be regulated by the Wnt pathway.[329]

Besides providing structure to the marrow space and a surface for cell adhesion, the microenvironment is important for hematopoietic cell homing, engraftment, migration, and the response to physiologic stress and homeostasis. Although the functional consequences of the

microenvironment ultimately must be defined by in vivo studies in mice, dissection of the cellular components of the microenvironment, definition of the cytokines that are produced by individual cells, and the nature of cell-cell interactions have been aided by in vitro models. Long-term bone marrow cultures provide an experimental approach for such studies.[330,331] Under these in vitro conditions, murine hematopoiesis can be maintained for 8 to 10 months and human hematopoiesis for 2 to 3 months.[330] An adherent layer consisting of fibroblasts, adipocytes, and macrophages is a crucial component of the culture system. Progenitor cells adherent to stroma are generally quiescent (dormant), whereas those in the nonadherent cell compartment are in active cell cycle.[331,332]

In vitro studies have demonstrated that stromal cells, including endothelial cells and fibroblasts, elaborate cytokines such as GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-11, KL, Flt-3 ligand, activin A, and basic fibroblast growth factor, which influence, alone or in combination, the growth of adjacent marrow progenitors.[330-333] In addition to positive regulators of replication and differentiation, stromal cells elaborate factors such as TGFβ, TPO, CXCL12L, interferon-γ, and TNF-α, which exert a negative influence on proliferation and may help maintain a dormant (noncycling) state.[331,332,334-336] Because some regulators inhibit differentiation along certain lineages but not others, there is an intriguing possibility that lineage-specific regulation within the microenvironment can be achieved through negative, rather than positive, factors.[337] Several cytokines are expressed in a transmembrane, form as well as a soluble (secreted) product. Others bind extracellular matrix, a mechanism that not only allows for high concentrations of a factor within the microenvironment that metabolically stabilizes these factors but also keeps them adjacent to developing progenitors.

Among the factors elaborated by stromal cells, KL has the most profound effect on erythropoiesis. Mice unable to synthesize KL die in utero because of severe anemia. Steel-Dickie (Sl^d) mice that are unable to make the membrane-restricted form of KL are viable but severely anemic, whereas other lineages in these animals are marginally affected or not affected by this defect.[338] The fact that erythropoiesis is abnormal, despite high levels of circulating EPO and the presence of soluble KL, suggests that normal erythroid differentiation and maturation require both a functional membrane-restricted KL/KIT and an EPO signaling pathway. Cross-phosphorylation of EPOR by KL may provide a basis for the predominately erythroid effect.[278] Furthermore, data suggest that tyrosine cross-phosphorylation of EPOR is sustained longer when cells are cultured on steel stromal cells engineered to express the membrane-restricted form of KL than cells expressing the soluble form.[339]

The soluble form of KL is produced by proteolytic cleavage of membrane KL and is released in the circulation. Soluble KL effectively supports erythroid maturation in vitro[340] but is dispensable for steady-state erythropoiesis, because targeted mutant mice expressing exclusively the more stable membrane isoform of KL, KL2, lacking the major proteolytic cleavage site, have normal hematocrit values.[341] However, these mice recover poorly from radiation-induced anemia.[341] In wild-type mice, sublethal radiation induced a transient fourfold increase in KL in the serum (from <0.5 up to >2 ng/mL), reaching a peak after 7 days. In contrast, the proteolytic-cleavage mutant $KL^{KL2/KL2}$ mice did not release soluble KL into the serum after sublethal radiation, and survival was significantly diminished because of anemia. These observations suggest that soluble KL plays an important regulatory role under conditions of stress.

The pathway(s) that regulate erythropoiesis under conditions of acute or chronic anemia are starting to emerge.[342] In mice, stress induces the formation of an erythroid permissive microenvironment in the spleen and other extramedullary sites. In fact, recent evidence suggests that, in addition to increasing EPO production by the kidney, in order to raise the levels of soluble KL in the serum and to activate GR response, this pathway activates spleen-specific microenvironmental cues (BMP4/hedgehog), which generate stress-specific hematopoietic compartments.[76,343] The identity of the hematopoietic stem cell niche in the spleen and the human equivalent of this cell are yet to be determined.

Besides cell-cytokine interactions, (paracrine) cell-cell adhesion and adhesion of cells to the extracellular matrix are important functions of the microenvironment.[344,345] Perhaps most studied are the β_1 integrins VLA4 and VLA5, which mediate the adherence of hematopoietic cells to stromal cells, fibronectin, or other components of the extracellular matrix.[345,346] In mice lacking β_1 integrins, hematopoietic stem cells fail to colonize the fetal liver during embryonic development,[347] and cells lacking α_4 integrin fail to contribute to normal hematopoiesis postnatally.[348] Antibodies to VLA4 or to the vascular cellular adhesion molecule 1 (VCAM1, a VLA4 ligand on endothelial cells) impair homing and lead to mobilization of progenitor cells and stem cells in adult mice and primates.[349-352] In in vitro studies, hematopoietic progenitors bind to specific domains of fibronectin in a differentiation-dependent manner (long-term culture-initiating cell and day 12 colony-forming unit–spleen in mice adhere mainly through the heparin-binding domain and CS-1). BFU-E and other progenitor cells adhere to both the cell-binding (Arg-Gly-Asp-Ser [RGDS]) and heparin-binding domains, whereas CFU-E preferentially bind the RGDS sequence, and reticulocytes fail to adhere to fibronectin.[328,353-356] This differential binding could influence the proliferation and especially the maturation and survival of developing erythroid cells, particularly under stress,[357] as well as the migration of progenitor cells in and out of the bone marrow cavity.[348,349] Hematopoietic cytokines/chemokines present in the microenvironment also can modulate the affinity of β_1 integrins for ligand,[358,359] adding complexity to the regulation of erythropoiesis within the marrow microenvironment.

Many observations suggest that hematopoietic progenitor cells at one stage of fetal development may not be supported by a hematopoietic microenvironment of a different ontogenetic stage. For example, cells present in the murine yolk sac are not able to repopulate adult recipients,[360] although they can repopulate newborn recipients with active fetal liver hematopoiesis.[361] Targeted disruption of CXCL12/SDF1, a member of the CXC chemokine family that is constitutively expressed by bone marrow stromal cells (i.e., reticular/endothelial cells or osteoblasts), leads to inhibition of marrow hematopoiesis, although fetal liver hematopoiesis is unaffected,[362] suggesting that this chemokine is important in maintaining normal bone marrow hematopoiesis. Other factors with distinct function on fetal versus adult hematopoiesis have also been described: Sox17 for fetal hematopoiesis[363] or TEL (translocation-ETS [E26 transformation-specific]-leukemia)[364] and Bmi-1 for adult hematopoiesis.[365]

Accessory cells, such as stromal cells, in addition to secreting cytokines, express adhesion molecules, and they may influence marrow hematopoiesis by their nonrandom distribution in the marrow cavity. T cells (along with mast cells) are the only source of IL-3 and, through secretion of TNF-α and interferon-γ, may negatively impact erythropoiesis. In histologic sections of normal marrow, islands of maturing erythroblasts (erythroblastic islands) often surround a central macrophage, termed a *nurse cell*.[366] Adhesion may be mediated through the binding of VLA4 (on erythroid cells) to VCAM1 (on central macrophages),[367] or through several other molecules.[368] These molecular interactions have been identified as being critical for erythroblastic island integrity. Erythroblast macrophage protein expressed on erythroblasts and macrophages mediates cell-cell attachment through homophilic binding, and erythroblast intercellular adhesion molecule 4 (ICAM4) links erythroblasts to macrophages by interacting with α_v integrin expressed in macrophages.[369-371] Mice with targeted deletion of erythroblast macrophage protein are severely anemic and die at an embryonic stage,[137] and $ICAM4^{null}$ mice[370] have markedly reduced erythroblastic islands. Of interest, retinoblastoma (RB)-deficient macrophages do not bind RB^{null} erythroblasts,[372] and failure of this interaction may mediate the defect in fetal liver erythropoiesis observed in RB^{null} mice. RB normally stimulates macrophage differentiation by counteracting inhibition of Id2 (a helix-loop-helix protein) on PU.1, a transcription factor crucial in macrophage differentiation. In addition to the aforementioned pathways, macrophage CD163 can serve as an erythroblast adhesion receptor in erythroblastic islands, promoting erythroid proliferation and/or survival.[373] More studies addressing the specific interactions between macrophages and erythroid cells that

promote erythroid differentiation are needed for definite conclusions regarding specialized "erythroid niches." Of note, tissue macrophages express RNA for EPO[374] and may also influence erythropoiesis through this mechanism.

The microenvironment is not only a passive surface for the adherence of progenitor cells; it exerts a crucial and interactive role in development and maturation. Some interactions are lineage (red cell) specific, whereas other interactions affect hematopoiesis more broadly. Stromal and accessory cells secrete cytokines and/or express them in a transmembrane form on their cell surface. Cytokines are retained via binding to components of the extracellular matrix. All components of the microenvironment are involved in adhesive interactions, some of which maintain quiescence (i.e., interactions of stem cells with endosteal surfaces[375,376]), whereas other cell-cell interactions or interactions of cells with matrix components induce proliferation and/or differentiation.[377-379] An individual progenitor cell, in an anatomic niche adjacent to certain stromal cells, accessory cells, and extracellular matrix molecules, likely responds to the sum of the signals that it uniquely receives. In this way, erythropoiesis, or the entire hematopoiesis, is influenced by the complexity of the interaction network.

ONTOGENY OF ERYTHROPOIESIS

During human development, distinct anatomic areas for production of erythroid cells are recruited sequentially, in a temporal succession that allows overlap (Fig. 24-3). In addition, parallel changes occur in the morphologic and functional properties of the erythroid cells themselves.

During the phase of embryonic erythropoiesis in the blood islands of yolk sac, aggregates of immature erythroid cells undergo maturation synchronously as a single cohort. Before their maturation is completed, they begin to circulate, and by gestational week 5 they are found in the vascular spaces of the rudimentary liver (Fig. 24-4). At about the same time, foci of immature erythroid cells emerge within the fetal liver as the fetal (or hepatic) phase of erythropoiesis commences.[380] From week 7 onward, the liver is progressively filled with erythroid precursors and becomes the dominant site of erythroid cell production until approximately gestational week 30. Although some red cell production can be found in the thymus, the spleen, or occasionally in the lymph nodes, these other sites are never dominant. However, recently placenta has been recognized as an important local erythropoietic site.[381] From month 6 onward, the cavities of long bones are invaded by vascular sprouts and become competent to support red cell development. Shortly after birth, all bone cavities are actively engaged in erythroid production, and the hepatic (fetal) phase of erythropoiesis comes to an end, as the final (adult) phase of erythropoiesis unfolds exclusively within the bone marrow.

In addition to the anatomic shifts in the sites of erythropoiesis are associated shifts in the phenotypic characteristics of erythroid cells. Embryonic erythroid cells (derived from the yolk sac) are large (approximately 200 μm), circulate as nucleated cells, and have a megaloblastic appearance (see Fig. 24-4). The fact that primitive erythroblasts of mammals, like erythroid cells of lower vertebrates, retain their nuclei at terminal stages of maturation may serve as an example of embryonic recapitulation of the phylogenetic evolution of the erythroid system. However, a study has identified the presence of enucleated megaloblasts in the blood of the mouse embryo at late stages of development, indicating that the enucleation process predominantly in the fetal liver is at least partially at work.[382] Other studies using genetic reporter models further suggest that embryonic (primitive) cells represent a stable cell population that persists through the end of gestation.[383] Fetal erythroid cells (produced in the fetal liver and later in fetal bone marrow spaces) are smaller than embryonic cells (approximately 125 μm) but have a macrocytic appearance compared with adult normocytic red cells (approximately 80 μm). However, like adult cells, fetal erythroid cells eject their nuclei during maturation.

Apart from variations in size and morphologic characteristics, embryonic and fetal erythroid cells differ from each other and from their adult counterparts in several other characteristics, including hormonal or growth factor requirements, proliferative status, and transplantation potential. For example, whereas fetal erythropoiesis is under the control of EPO,[384] the extent of EPO's influence on embryonic erythropoiesis is disputed. Most convincing are the results of EPO/EPOR knockouts[190] that showed only partial effects on embryonic erythropoiesis, in contrast to fetal erythropoiesis. Single-lineage transcriptosome analyses indicate that TGFβ may represent a primary regulator of embryonic erythropoiesis.[385] Evidence suggests that precursor cells from the extraembryonic mesoderm are dependent on EPO for proliferation and erythroid differentiation.[386] EPO levels increase between weeks 9 and 32 of gestation, and fetuses respond to hypoxia or anemia with increased EPO as early as 24 weeks. Fetal erythroid progenitors when studied in vitro appear more sensitive to EPO and KL than adult progenitors. In contrast, their in vitro response to lymphokines (e.g., IL-3 or GM-CSF) is minimal compared to that of adult erythroid progenitors.[387,388] Of note, in the early stages of fetal liver erythropoiesis, mainly erythroid differentiation/maturation is promoted.[241] Progenitors committed to other lineages are abundant in the fetal liver, but few mature cells (granulocytes, megakaryocytes) from other lineages are seen. In addition to their heightened sensitivity to EPO, fetal erythroid progenitors and precursors are characterized by high proliferative potential and shorter doubling times than adult cells when cultured in vitro.[387,389] The dependency of stem/progenitor cells on KL changes during ontogeny. Although generation of repopulating stem cells (C-KIT$^+$/Sca1$^+$/Thy1^{lo}/Lin$^-$) and colony-forming unit–spleen is minimally

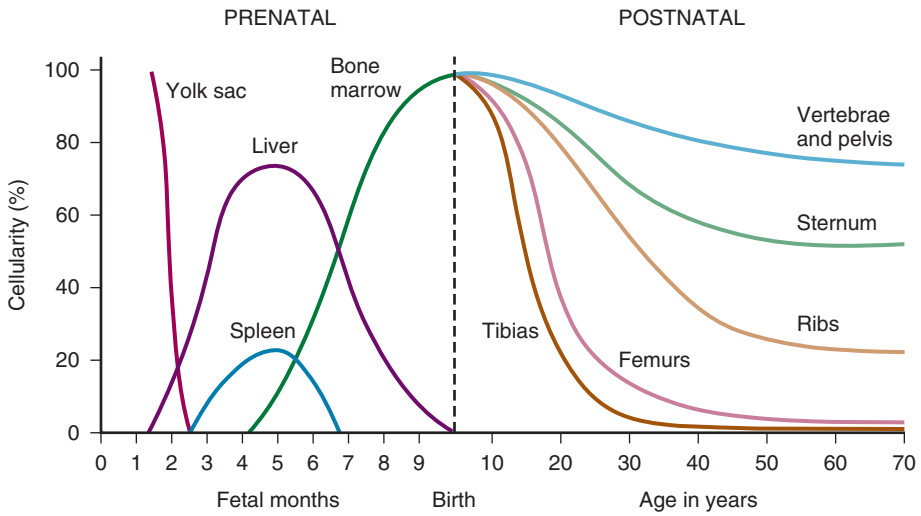

Figure 24-3 SITES OF HEMATOPOIESIS DURING FETAL DEVELOPMENT AND AFTER BIRTH. Only erythroid cells and possibly lymphocytes are generated by the yolk sac and early embryo. Significant megakaryocytopoiesis and granulopoiesis develop at 4 to 5 months. After birth, hematopoiesis occurs in the sinusoidal cavities of the tibias, femurs, and axial skeleton. *(Modified from Erslev A, Gabuzda T:* Pathophysiology of blood, *ed 2, Philadelphia, 1979, WB Saunders.)*

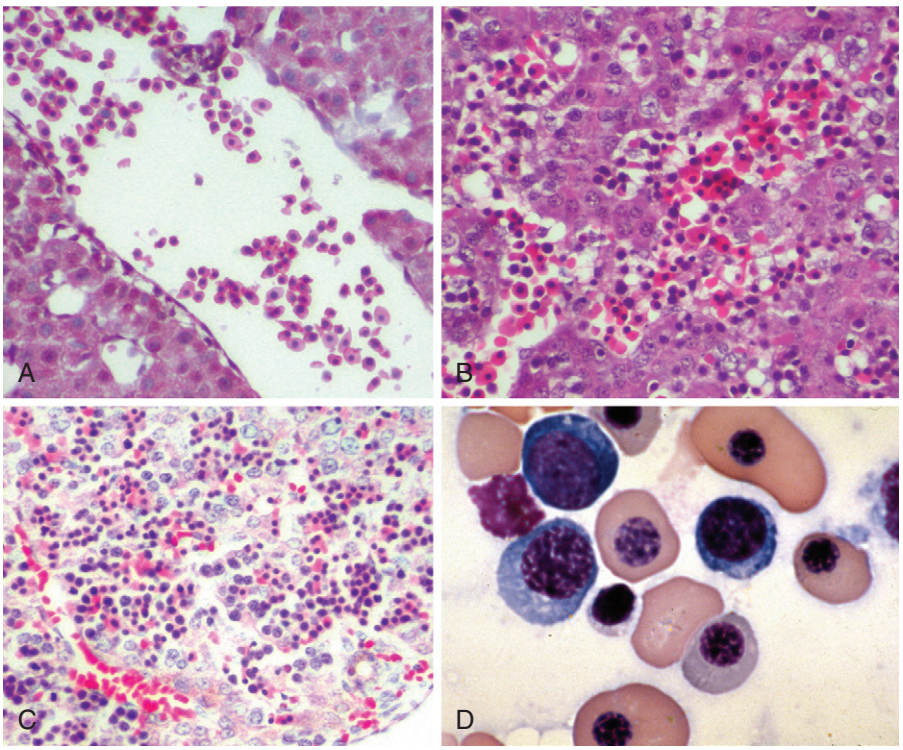

Figure 24-4 EMBRYONIC/FETAL ERYTHROPOIESIS. **A,** Section of an 8-mm embryo depicting a portion of hepatic parenchymal cells with embryonic erythroblasts present within primitive sinusoidal cavities. **B,** At 6 to 8 weeks, discrete aggregates of definitive erythroblasts appear within the liver parenchyma, whereas mature embryonic erythroblasts persist in well-developed sinusoids. **C,** Definitive erythroblasts are spread throughout the liver (100-day fetus). **D,** Cytologic spread from disaggregated fetal liver cells of a 55-day embryo. Characteristic form of embryonic erythroblasts and immature (basophilic) definitive erythroblasts is shown. (**A** to **C,** hematoxylin-eosin stain; **D,** Wright-Giemsa stain.)

affected during fetal life in mice that cannot produce KL, adult steel-Dickie (Sl/Sl^d) mutant mice (which produce only some soluble KL) display greatly impaired erythropoiesis and hematopoiesis, suggesting that the KL/C-KIT pathway plays a role in the recruitment and self-renewal behavior of adult stem cells in vivo.[390,391] The long-term transplantation potential is impaired in cells with mutations of C-KIT kinase activity.[391] Transplantable stem cells from the yolk sac, in contrast to fetal liver cells, cannot engraft adult recipients, because of altered homing behavior or inability of bone marrow to support their development,[361] as suggested by their engraftment in neonatal liver.[392] The homing properties of fetal stem cells transplanted into adult irradiated recipients were found to be inferior to those of their adult counterparts.[393] Whether this finding is related to their increased cycling or other reasons is unclear. However, fetal liver stem cells, despite their reduced homing potential,[393] have higher engraftment levels, likely because of their proliferative prowess compared to adult stem cells.[394]

The surface antigenic profiles of erythroid progenitors and precursors are distinct at each ontogenic stage. For example, HLA class I and class II antigens are not detected in embryonic erythroid progenitor cells but reach adult levels at approximately gestational week 9.[395] $CD34^+$ hematopoietic progenitors present in yolk sac express Mac-1 but are negative for stem cell antigen 1 (Sca-1), which is expressed in fetal and adult $CD34^+$ murine progenitor cells.[396] On the other hand, adult $CD34^+$ progenitors lack Mac-1 and AA4.1, which are expressed in fetal $CD34^+$ progenitor cells. Fetal BFU-E and CFU-E express similar levels of HLA class II antigens, whereas adult CFU-E are largely devoid of these antigens.[395,397] β_1 integrins, especially $\alpha_4\beta_1$ and α_5, are expressed widely in all hemopoietic cells, including nucleated erythroid cells. However, in the latter, they display a differentiation-dependent, developmentally segregated pattern of expression, because they are absent in embryonic murine erythroblasts,[398] and among adult cells, stem/progenitor cells express them in a constitutively active form in contrast to more mature cells.[399-401] Fetal red cells display a straight, unbranched polylactosaminyl chain (i antigen) on their surface, whereas in adult cells, this structure, which bears ABH blood group determinants, is highly branched (I antigen).[124] The enzymatic activity of several enzymes in the glycolytic pathway is greater in fetal than in adult red cells.[402] In contrast, carbonic anhydrase levels are very low during intrauterine and early neonatal life.[403] Distinct isozyme patterns for several enzymes (i.e., phosphoglycerate kinase, acetylcholinesterase) also distinguish fetal from adult red cells.[404,405]

The most widely studied changes during red cell ontogeny are the shifts or "switches" in globin types. Embryonic erythroblasts are characterized by their avid accumulation of iron, which is stored as ferritin[406] (0.3% to 1% of total protein) and by the synthesis of the unique hemoglobins Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), and hemoglobin Portland ($\zeta_2\gamma_2$). The ζ- and ε-globin chains are embryonic α-like and β-like chains, respectively.[88] These three embryonic types of hemoglobin are most likely synthesized in succession, because the concentration of Gower I is highest in smaller embryos. Thus a switch from ζ- to α- and ε- to γ-globin gene production begins during the embryonic phase of erythropoiesis but is not complete until fetal erythropoiesis is well established. During the transition from yolk sac to fetal liver erythropoiesis (6 to 9 weeks), erythroid precursors within the fetal liver coexpress embryonic (ζ- or ε-) and fetal (α- or γ-) globin both in vivo and in vitro.[407,408] The predominant type of hemoglobin synthesized during fetal liver erythropoiesis is HbF ($\alpha_2\gamma_2$), with a high proportion of $\gamma^G:\gamma^A$ (7:3). Adult HbA ($\alpha_2\beta_2$), which is detectable at the earliest stages of fetal liver erythropoiesis, is synthesized as a minor component throughout this period. However, HbA_2 ($\alpha_2\delta_2$), which is a minor hemoglobin in the adult, is undetectable in these early stages. From about gestational week 30 onward, β-globin synthesis steadily increases so that, by term, 50% to 55% of hemoglobin synthesized is HbA. By 4 to 5 weeks of postnatal age, 75% of the hemoglobin is HbA. This percentage increases to 95% by 4 months as the fetal-to-adult hemoglobin switch is completed. HbF levels in circulating red cells are at a plateau for the first 2 to 3 weeks (as a result of the decline in total erythropoiesis that follows birth), but the HbF level gradually declines so that normal levels (<1%) are achieved by 200 days after birth.[409]

Several in vitro and in vivo approaches have been used to study the basis of globin switching through development. Beyond its biologic interest, rigorous research in this area was propelled by the possibility of manipulating globin switching to increase HbF production in adults and ameliorate the clinical symptoms of disorders of the β-globin locus (e.g., sickle cell anemia, thalassemia).

Transplantation experiments and ablative endocrine maneuvers in the sheep model have failed to provide convincing support for the effects of environmental or humoral factors on the switching process, although some modulation of the rate of switching was seen in these models.[410,411] Similar conclusions were reached with transplantation of human fetal liver cells to adult recipients.[412,413] The most important determinant of fetal-to-adult hemoglobin switching seems to be postconceptual age, with the sharpest period for transition between 30 and 52 weeks. The fetal-to-adult switch appears to be unaffected by the time at which birth occurs or by changes in the kinetics of erythropoiesis induced by perinatal hemolysis.[414] A delay in switching usually is observed in cases of general developmental retardation, in patients with certain chromosomal abnormalities (e.g., trisomy 13), and in diabetic infants because of increased circulating levels of α-aminobutyric acid, which directly affects HbF synthesis.[415] Integration of data from studies using in vitro and in vivo approaches indicates that developmental control of globin switching is intrinsic to erythroid cells. Stage-specific transcriptional forces with negative or positive influences (or both) on specific globin genes may provide the molecular basis for differential transcriptional activity during development. This view is favored by experiments in transgenic mice[416] and in heterokaryons (produced by fusion of human with mouse cells),[417] as well as by isolation of stage-specific transcription factors in other erythroid systems (e.g., avian).[418] Furthermore, because α-like and β-like globin genes are activated sequentially in the order of their location in chromosome 11 or 16, respectively, it is possible that polarity of the transcriptional activity and globin promoter competition for the locus control region and developmental stage–specific transcription factors contribute to this regulation.[419]
